In the United States, 75% of children with ESRD require a period of dialysis before transplantation can be performed. It is recommended that plans for renal replacement therapy be initiated when a child reaches stage 4 CKD. The optimal time to actually initiate dialysis, however, is based on a combination of the biochemical and clinical characteristics of the patient including refractory fluid overload, electrolyte imbalance, acidosis, growth failure, or uremic symptoms, including fatigue, nausea, and impaired school performance. In general, most nephrologists attempt to initiate dialysis early enough to prevent the development of severe fluid and electrolyte abnormalities, malnutrition, and uremic symptoms. Preemptive transplantation before initiation of dialysis is increasingly being utilized.

The selection of dialysis modality must be individualized to fit the needs of each child. In the United States, two thirds of children with ESRD are treated with peritoneal dialysis, whereas one third are treated with hemodialysis. Age is a defining factor in dialysis modality selection: 88% of infants and children from birth to 5 yr of age are treated with peritoneal dialysis, and 54% of children >12 yr of age are treated with hemodialysis.

Peritoneal dialysis is a technique that employs the patient's peritoneal membrane as a dialyzer. Excess body water is removed by an osmotic gradient created by the high dextrose concentration in the dialysate; wastes are removed by diffusion from the peritoneal capillaries into the dialysate. Access to the peritoneal cavity is achieved by a surgically inserted, tunneled catheter.

Peritoneal dialysis may be provided either as continuous ambulatory peritoneal dialysis or as an automated therapy using a cycler (continuous cyclic peritoneal dialysis, intermittent peritoneal dialysis, or nocturnal intermittent peritoneal dialysis). The majority of U.S. children treated with peritoneal dialysis use cycler-driven therapy, which allows the child and family to be free of dialysis demands during the waking hours. The exchanges are performed automatically during sleep by machine. This permits an uninterrupted day of activities, a reduction in the number of dialysis catheter connections and disconnections (which decreases the risk of peritonitis), and a reduction in the time required by patients and parents to perform dialysis, reducing the risk of fatigue and burnout. Because peritoneal dialysis is not as efficient as hemodialysis, it must be performed daily rather than 3 times weekly. Table 535-8 outlines the benefits of peritoneal dialysis.

Hemodialysis, unlike peritoneal dialysis, is usually performed in a hospital setting. Children and adolescents typically have 3 treatments (3-4 hr each) per wk during which fluid and solute wastes are removed. Access to the child's circulation is achieved by a surgically created arteriovenous fistula, graft, or indwelling subclavian or internal jugular catheter.

Bibliography is available at Expert Consult.

Table 535-8	Merits of Peritoneal Dialysis in Pediatric Patients with End-Stage Renal Disease
ADVANTAGES	
Ability to perform dialysis treatment at home	
Technically easier than hemodialysis, especially in infants	
Ability to live a greater distance from medical center	
Freedom to attend school and after-school activities	
Less-restrictive diet	
Less expensive than hemodialysis	
Independence (adolescents)	
DISADVANTAGES	
Catheter malfunction	
Catheter-related infections (peritonitis, exit site)	
Impaired appetite (due to full peritoneal cavity)	
Negative body image	
Caregiver burnout

Chapter 536
Renal Transplantation
Minnie M. Sarwal

Kidney transplantation is the optimal therapy for children with end-stage renal disease (ESRD). Five yr survival rates in children who receive a kidney transplant are greater than survival rates of those who remain on hemodialysis or peritoneal dialysis. Children and adolescents with ESRD have special needs that differ from adults, including the need to achieve normal growth and cognitive development. Successful transplantation leads to improvement in their linear growth and allows them to attend school and be free of dietary restrictions. Immunosuppression protocols that employ steroid minimization or avoidance after transplantation demonstrate dramatic improvements in growth patterns for young children after transplantation. Improvements in surgical techniques and a reduction in the early complications of thrombosis have given young children the best long-term outcomes of all age groups among transplant recipients.

INCIDENCE AND ETIOLOGY
The incidence of ESRD in pediatric patients in the United States varies by age group (Table 536-1). There is an adjusted incident rate of 14.4 per million population for ages 0-19 yr.

The etiology of ESRD in children varies significantly by age (Table 536-2). Congenital, hereditary, and cystic diseases cause ESRD in more than 52% of children 0-4 yr of age, whereas glomerulonephritis and focal segmental glomerulosclerosis (FSGS) account for 38% of cases of ESRD in patients 10-19 yr of age. The most common diagnosis in children with *transplanted kidneys* is structural disease (49%), followed by various forms of glomerulonephritis (14%) and FSGS (12%).

INDICATIONS
Almost all children with ESRD are considered to be candidates for renal transplantation. There are very few absolute contraindications for pediatric kidney transplantation. Relative contraindications include children with preexisting metastatic malignancy or HIV. Patients with remission of malignancy off maintenance treatment for a minimum of 2 yr may be reconsidered on an individual basis for transplantation, with close posttransplantation surveillance. Similarly, patients with autoimmune diseases resulting in ESRD are candidates for transplantation after a period of immunologic quiescence of the primary disease for a period of at least 1 yr before transplantation. Another relative contraindication includes severe neurologic dysfunction, but the wishes of the parents and the potential for rehabilitation must be considered.

Table 536-1 Incident Rates of Reported ESRD in the United States

AGE RANGE (YR)	ADJUSTED INCIDENT RATES* PER MILLION POPULATION
0-4	9.5
5-9	6.1
10-14	13
15-19	29

*Rates are adjusted for sex and race.

Table 536-2 Common Causes of ESRD in Pediatric Transplant Recipients (N = 9854)

CAUSES	% OF RECIPIENTS
Aplasia, hypoplasia, dysplasia	15.9
Obstructive uropathy	15.6
Focal segmental glomerulosclerosis	11.7
Reflux nephropathy	5.2
Chronic glomerulonephritis	3.3
Polycystic disease	2.9
Medullary cystic disease	2.8
Hemolytic-uremic syndrome	2.6
Prune belly syndrome	2.6
Congenital nephrotic syndrome	2.6
Familial nephritis	2.3
Cystinosis	2.0
Idiopathic crescentic glomerulonephritis	1.7
MPGN type I	1.7
Berger (IgA) nephritis	1.3
Henoch-Schönlein nephritis	1.1
MPGN type II	0.8

ESRD, end-stage renal disease; MPGN, membranoproliferative glomerulonephritis.
Data from the North American Pediatric Renal Trials and Collaborative Studies, https://web.emmes.com/study/ped/.

Renal transplantation is considered for any child when renal replacement therapy is indicated. In children, dialysis may be required for a period before transplantation to optimize nutritional and metabolic conditions, to achieve an appropriate size in small children, or to keep a patient stable until a suitable donor is available. For young infants, a recipient may need to weigh at least 8-10 kg to minimize the risk for vascular thrombosis and to accommodate an adult-size kidney. This can require a period of dialysis support until the child is at least 12-18 mo of age. Transplantation with an adult-size kidney has been successful in children who weighed <10 kg or were <6 mo of age.

Preemptive transplantation (i.e., transplantation without prior dialysis) continues to account for approximately 25% of all pediatric renal transplants, based mostly on a desire by the child and the family to avoid dialysis. There may be a small benefit in allograft outcome if transplantation occurs without prior dialysis, which might relate to a lower incidence of infections and cardiovascular risk factors. Preemptive renal transplant should be considered when the glomerular filtration rate (GFR) is <10-15 mL/min/1.73 m^2 and with symptomatic ESRD or rapidly declining GFR and need for dialysis within 6-12 mo. The rates of preemptive transplantation differ moderately for different age groups, being 20% for recipients age ≤2 yr, 24% for age 2-5 yr, 28% for age 6-12 yr, and 22% for age 13-17 yr.

CHARACTERISTICS OF DONORS AND RECIPIENTS

Almost half of all pediatric kidney transplants come from living donors. The highest rates of transplantation are in the 5-9 yr old group, with 40 live donor transplants and 46 cadaver donor transplants performed per 100 dialysis patient-years. The Organ Procurement and Transplantation Network (OPTN) provides preference for children waiting for a deceased-donor renal transplant. Owing to improved outcomes in deceased-donor pediatric transplantation using donors 5-35 yr of age, OPTN in 2005 implemented a pediatric kidney allocation policy that gave priority for kidneys from deceased donors <35 yr of age. These kidneys were assigned to recipients <18 yr, after 0 mismatch transplants, recipients with a panel reactive antibody >80, or candidates receiving a kidney with a nonrenal origin. This policy shortened the wait time for children versus adults and is associated with improved outcomes.

Living-donor kidney transplantation graft survival has improved over the years, and from 2003-2007 the graft survival rate in living-donor renal transplants was 96.1%, unchanged from the 1999-2002 rate of 95.9%. Graft survival rates for deceased donors from 2003-2007 are 94.4%, also improved from 92.7% in 1999-2002. For children awaiting deceased-donor renal transplants the goals are to minimize waiting times, transplanting kidneys into children 0-6 yr of age within 6 mo, children 7-12 yr within 12 mo, and children 12-18 yr within 18 mo.

EVALUATION AND PREPARING FOR TRANSPLANTATION

The team approach includes evaluations by a transplantation surgeon, nephrologist, nutritionist, social worker, psychologist, financial counselor, pretransplantation nurse, and dialysis nurse (if the patient is undergoing dialysis).

Primary renal disease can recur in a number of renal diseases, but it is not a contraindication to transplantation. Recurrent disease in the renal graft accounts for graft loss in almost 7% of primary transplantations and 10% in repeat transplantations.

With FSGS and primary oxalosis, patients are at risk for major renal function impairment with recurrence of disease. Grafts in approximately 20-30% of patients with the diagnosis of FSGS fail because the disease recurs. In patients with the original disease of FSGS whose grafts fail, the mean time to failure is 17 mo. Alport syndrome can recur as an anti–glomerular basement membrane (anti-GBM) glomerulonephritis in approximately 3-4% of patients after transplantation and lead to graft loss. Histologic evidence of recurrence of membranoproliferative glomerulonephritis type I varies widely, from 20% to 70%, and graft loss can occur in ≤30% of cases. Histologic recurrence of membranoproliferative glomerulonephritis type II disease occurs in virtually all cases, with graft loss in ≤50% cases. Histologic recurrence with mesangial immunoglobulin (Ig) A deposits is common and occurs in about half of the patients with IgA nephropathy and in approximately 30% of patients with Henoch-Schönlein purpura. Congenital nephrotic syndrome rarely recurs after transplantation, although patients can develop antinephrin antibodies and present with nephrotic syndrome. Some cases (~25%) of nephrotic syndrome after transplantation are likely de novo. Membranous nephropathy occurs very rarely in children. The recurrence rate after kidney transplantation for patients who have been treated for Wilms tumor is approximately 13%.

Owing to the high risk of developing Wilms tumor, patients with Denys-Drash syndrome should undergo bilateral nephrectomy before transplantation. Other *indications for bilateral native nephrectomies* include hyposthenuria with polyuria, significant proteinuria, and severe hypertension resistant to medical management. Nephrectomies are also indicated in cases such as polycystic kidney disease, where more room may be needed to place the transplanted kidney and to create space in the abdominal cavity to improve feeding tolerability and the infant's ability to thrive.

Failure to maintain adequate perfusion of the adult-size kidney, secondary to a "perfusion steal" by the native kidneys results in a histologic picture of "chronic" acute tubular necrosis and a negative impact on graft function.

Urologic problems, such as vesicoureteral reflux, posterior urethral valves, abnormal urinary bladders, and/or neurogenic bladders, should be addressed before surgery. Malformations and voiding abnormalities (e.g., neurogenic bladder, bladder dyssynergia, remnant posterior urethral valves, and urethral strictures) should be identified and repaired if possible. Children with urologic disease and renal dysplasia often require multiple operations to optimize urinary tract anatomy and function. Such procedures include ureteric reimplantation to correct vesicoureteral reflux, bladder augmentation or reconstruction, creation of a vesicocutaneous fistula by using the appendix to provide a simple, continent, and cosmetically acceptable way for intermittent

catheterization (Mitrofanoff procedure), and excision of duplicated systems or ectopic ureteroceles that could cause recurrent infections. There are reports of excellent outcomes often being achieved in posterior urethral valve bladders by following a staged procedure of initial valve resection to limit any injury to the posterior urethra, and bladder rehabilitation, without the requirement of augmentation, by a process of regimented double voiding.

A comprehensive **nutritional assessment** needs to be done to ensure that optimal nutritional status is achieved before transplant. Many children with ESRD and especially those on dialysis require nutritional supplements to provide them with sufficient protein and calories. Infants and young children on dialysis often require nasogastric or gastric tube feedings to overcome decreased oral intake from nausea and anorexia due to uremia. Optimal outcomes result from transplanting adult-size kidneys from living donors when the child weighs ≥10 kg.

Bone disease needs to be evaluated for and treated before transplantation. Secondary hyperparathyroidism needs to be treated before transplant to avoid posttransplant urinary phosphate wasting and hypercalcemia. High calcium phosphorus product before transplantation leads to vascular stiffness and calcifications, increasing the patient's risk for cardiovascular disease.

In the United States, >25% of the mortality in children on maintenance dialysis is a result of **cardiovascular disease**. Cardiac death is the leading cause of death in young patients after transplant in childhood. Therefore, evaluation of cardiac function is required before a kidney transplant in a pediatric patient to be sure that patient has sufficient cardiac function to tolerate the large fluid load that accompanies kidney transplantation. All patients being evaluated for kidney transplant have at least an echocardiogram and electrocardiogram. Hypertension is common and can result from fluid overload and/or intrinsic native renal disease. Blood pressure needs to be under optimal control before transplant. If blood pressure cannot be controlled with medical management, bilateral nephrectomy may need to be performed before transplant to control the hyperreninemic response from the failing kidneys.

Anemia needs to be treated before transplantation. Most patients are taking erythropoietin, folate, and iron to maintain goals for hemoglobin levels between 11 and 12 g/dL. Blood transfusions should be avoided owing to concerns for sensitizing the patient to human leukocyte antigens before transplant. If a blood transfusion is required, patients should receive cytomegalovirus negative, leukoreduced red blood cells. Blood should not be irradiated owing to concerns for trauma to the cells and potential for increased antigen exposure.

Evaluation for **venous thrombosis** and **hypercoagulable states** is important before renal transplantation. The third leading cause of graft failure is vascular thrombosis; the leading causes are chronic (34.9%) and acute (13.1%) rejection. Risk factors for graft thrombosis include surgical technique, perfusion and reperfusion injury of graft, young donor age (<2 yr), young recipient (<5 yr), cold ischemia time >24 hr, arterial hypotension, prior history of peritoneal dialysis, and/or hypoperfusion of adult kidney transplant in a small child. Particularly in the young recipient, before transplantation, there needs to be evaluation for thrombosis of iliac vessels or inferior vena cava if the patient has had previous surgery or central line placement. Femoral line catheterizations greatly increase the risk for inferior vena cava thrombosis. Children who have large protein losses, such as from nephrotic syndrome and/or peritoneal dialysis, can be at increased risk for thrombosis because of protein loss, such as protein S, protein C, and antithrombin III. Doppler ultrasound, computed tomographic angiography, and magnetic resonance angiography have all been used to evaluate vessels. Magnetic resonance angiography has been used less owing to the concern about exposure to gadolinium and nephrogenic systemic fibrosis. In patients with renal compromise receiving contrast media, intravenous hydration is needed before and after the study for patients with residual renal function, acidosis should be corrected before giving contrast, and *N*-acetyl cysteine should be administered before and after the CT angiogram to reduce the risk of contrast nephropathy. If the patient is on dialysis, dialysis clearance can be done after contrast administration; hemodialysis is the optimal method for clearance.

Infections need to be identified and treated before transplantation. Infectious disease screening includes a complete history of household contacts with treatment for active or latent tuberculosis, vaccine history for varicella and pertussis, travel history within the past 2 yr and/or if there was significant time spent in another country, history of bacille Calmette-Guérin, animal and/or insect exposure, sexual activity, and consumption of high-risk foods such as unpasteurized products. Screening includes tuberculosis skin test (purified protein derivative), cytomegalovirus IgG, Epstein-Barr virus (EBV) antibody panel, varicella titer, measles antibody, hepatitis B serologies, hepatitis C antibody, HIV, and toxoplasmosis. Additional testing for patients who lived in or visited the central valleys of California, Utah, Nevada, Arizona, and/or New Mexico includes *Coccidioides* immunodiffusion. Patients from the Ohio River valley should also have *Histoplasma* antibody checked. Patients from Mexico should have *Coccidioides* immunodiffusion, *Histoplasma* antibody, and ova and parasite screen to evaluate for *Strongyloides.* Those from South America should have *Coccidioides* immunodiffusion, *Histoplasma* antibody, and *Toxoplasma* antibody. Sexually active patients should also be screened for syphilis, gonorrhea, HIV, and *Chlamydia.*

Immunizations need to be up to date before transplantation. All live vaccines need to be given before transplantation because these vaccines should not be given to immunosuppressed patients. Therefore, measles-mumps-rubella and varicella should be given before transplant and antibody titers should be checked to monitor for response. Measles-mumps-rubella may be given as early as 6 mo of age. Inhaled influenza vaccine should not be given to transplant patients, family members, or healthcare providers.

Psychiatric evaluation should be performed before transplantation to evaluate patients' and their families' ability to cope with the stressors that accompany caring for a child with a kidney transplant. A psychologist should also evaluate the patient and their caregivers for depression, substance abuse, and/or noncompliance so that problems can be identified and managed before kidney transplantation. If noncompliance is identified or anticipated, interventions should be in place before transplantation. These should include social and psychiatric interventions, where possible.

Children need 2 ABO blood types checked before being listed for a kidney transplantation and a donor should be sought who shares HLA-A, HLA-B, and/or HLA-DR antigens. The 2008 North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) data have shown increased risk for rejection and graft failure with 2-DR mismatch compared to a 0-DR mismatch. The recipient's blood is also checked to see if the patient is sensitized. Patients can become sensitized by prior transplant, blood transfusions, sepsis, and/or pregnancy.

IMMUNOSUPPRESSION

Most pediatric kidney transplant centers employ a combination of drug therapy consisting of a calcineurin inhibitor and corticosteroids with or without an antiproliferative agent. Approximately 80% of transplantation patients receive a 3-drug regimen at 6 mo after transplantation. The rationale for this combination therapy in children is to provide effective immunosuppression and at the same time minimize the toxicity of any single drug.

Induction Therapy

Induction therapy is commonly used in pediatric renal transplant recipients to prevent acute rejection. Graft survival rates are higher in patients treated with antilymphocyte induction therapy. Acute rejection episodes are approximately 30% less frequent and tend to occur later. Induction therapy may consist of T-cell antibodies, interleukin-2 receptor antibodies, and/or therapies that target B cells.

T-Cell Antibodies

Antithymocyte globulin (ATGAM) and Thymoglobulin are polyclonal antibodies that should be given intravenously through a central line to avoid sclerosis and injury to smaller vessels. These medications are

used to prevent the development of the first rejection. Thymoglobulin is polyclonal antibodies against human T-lymphocyte antigens resulting in a rapid depletion of T lymphocytes. Some limit the use of Thymoglobulin induction to sensitized high-risk patients or patients who have concerns for delayed graft function and want to avoid high calcineurin inhibitor levels in the early postoperative period. Dosage is 1.5-2.0 mg/kg/dose, with daily monitoring of $CD3^+$ subsets; the dose should not be given if the $CD3^+$ count exceeds 20 cells/mm^3.

OKT3 is a monoclonal antibody that is also given daily for 10-14 days. Studies have not shown a clear advantage using OKT3.

Interleukin-2 Receptor Antibodies

Monoclonal antibodies, such as basiliximab and daclizumab, chimeric or humanized monoclonal anti-CD25 antibodies, prevent T-cell proliferation but do not cause T-cell depletion. Basiliximab is given on day 0 and day 4 of the transplant as 12 mg/m^2/dose in children. Daclizumab is given on day 0 and then every 2 wk for a total of 5 doses at 1 mg/kg/dose in patients with steroid-based immunosuppression. Patients who are steroid free receive a 2 mg/kg dose on day 0 and the remaining doses at 1 mg/kg at wk 2, 4, 6, 8, 11, 15, 19, and 23. This provides the patient with extra immunosuppression for 3 mo for steroid-based patients and 6 mo for steroid-free patients. Patients tend to tolerate IL-2 receptor antagonists well. With the withdrawal of daclizumab from the market because of manufacturing deficits, many pediatric transplantation programs are using basiliximab or a short course (3 days) of Thymoglobulin at 1.5 mg/kg/day for children at low risk of sensitization and the recommended dosing of Thymoglobulin (5-7 days) or alemtuzumab for children at high risk of sensitization (see below).

Alemtuzumab (Campath-1H) is a monoclonal antibody against CD52 antigen present on T and B cells, monocytes, and natural killer cells. The pediatric data on the use of alemtuzumab show promising results.

Other Induction Therapies

Other induction therapies for highly sensitized patients include targeting B cells and/or removing neutralizing antibodies by using rituximab against the CD20 epitope on early-and intermediate-lineage B cells, the proteosome inhibitor bortezomib, and plasmapheresis and/or high-dose intravenous immunoglobulin for removing donor-specific antibodies.

Belatacept is a fusion protein composed of the Fc fragment of a human IgG_1 linked to the extracellular domain of CTLA-4, which is a molecule crucial for T-cell costimulation, selectively blocking the process of T-cell activation. Belatacept usage extends from induction to limited maintenance therapy, and is intended to provide optimal immunosuppression and limiting of the toxicity generated by standard immune-suppressing regimens, such as calcineurin inhibitors, thus limiting fibrosing graft injury and improving renal function. Complications include a higher incidence and grade of acute rejection episodes and a higher incidence of posttransplant lymphoproliferative disorders, with greatest risk in EBV seronegative recipients.

Maintenance Immunosuppression

For maintenance immunosuppression, calcineurin inhibitors, mycophenolate mofetil (MMF), steroids, azathioprine, and/or rapamycin may be used. Most pediatric kidney transplant recipients are maintained with a triple-immunosuppressant regimen. Central to many current pediatric immunosuppressive regimens is a calcineurin inhibitor (cyclosporine or tacrolimus) in combination with steroids and an adjunctive antiproliferative agent (azathioprine, sirolimus, or MMF). MMF is used as the adjunctive agent in more than two thirds of the pediatric kidney transplants performed. Sirolimus is used in 10-15%, and azathioprine is used in only approximately 2%. Corticosteroids continue to be used in approximately 80-85% of transplant recipients.

Calcineurin Inhibitors

The side-effect profile of **cyclosporine** in children is similar to that seen in adults, but the impact on children is more pronounced. Hypertrichosis, gingival hyperplasia, and coarsening facial features may be particularly troublesome in children. Hispanic and African-American children appear to be at higher risk for significant hypertrichosis. In the adolescent population, especially girls, these side effects can cause severe emotional distress, possibly leading to noncompliance. Seizures, although uncommon, are observed more commonly in children treated with cyclosporine than in adults. Children are likely to develop hypercholesterolemia and hypertriglyceridemia and may be candidates for lipid-lowering agents. Hyperglycemia occurs in <5% of children treated with cyclosporine.

The hyperlipidemia associated with cyclosporine and other immunosuppressive agents is also absent with **tacrolimus**. On the other hand, posttransplantation glucose intolerance, tremor, alopecia, and mild sleep disturbances are more common with tacrolimus. Historically, **posttransplant lymphoproliferative disease** has been significantly more common in children receiving tacrolimus. The lack of cosmetic side effects makes tacrolimus a very attractive alternative for children. This is especially true for young adolescents and female patients, in whom the cosmetic side effects can lead to noncompliance.

Direct comparative data in pediatrics between cyclosporine and tacrolimus are limited. The published results comparing these 2 agents show that overall acute rejection rates at 6 mo were 59.1% versus 36.9% for cyclosporine and tacrolimus, respectively. In the tacrolimus group, graft function was better at 1 yr after transplantation. The mean total steroid dose from time of transplant to 6 mo posttransplantation was significantly lower in the tacrolimus group. The overall safety profiles of the 2 calcineurin inhibitors were equivalent, with essentially no difference in posttransplant lymphoproliferative disorder or in diabetes requiring insulin treatment. The combination of drugs (tacrolimus and sirolimus) may be the biggest risk factor for PTLD.

Mycophenolate Mofetil

MMF is the morpholinoethylester prodrug of mycophenolic acid, an inhibitor of de novo purine synthesis. MMF is part of the initial maintenance immunosuppression regimen in approximately 66% of U.S. pediatric renal transplant recipients. It has largely replaced azathioprine. Acute rejection rates with MMF are approximately 20-30% when used with cyclosporine and corticosteroids. When MMF is used with tacrolimus and/or humanized monoclonal antibodies to the IL-2 receptor, lower rejection rates are usually seen.

The use of MMF has often facilitated the use of a lower dose of corticosteroids after transplantation. It has also proved useful in calcineurin inhibitor–sparing protocols, in which MMF is combined with sirolimus and corticosteroids. In steroid-avoidance regimens in kidney transplantation, the bioavailability of mycophenolic acid has been found to be greater than when the drug is used with steroids. This has allowed reduced dosing of MMF when combined with steroid avoidance in children. The absence of nephrotoxicity, hyperlipidemia, and hepatotoxicity has also contributed to the usefulness of MMF.

Gastrointestinal and hematologic side effects can be troublesome. Most of these instances can be treated with a dosage reduction and/or brief discontinuation of the drug, with resumption after 7-14 days at a lower dose. Enteric-coated mycophenolic acid has been shown to decrease the upper gastrointestinal side effects of MMF in adult transplant recipients.

Sirolimus

Sirolimus, an inhibitor of the mammalian target of rapamycin, is used primarily as an adjunctive immunosuppressive agent in combination with a calcineurin inhibitor. It is used in approximately 10-15% of pediatric renal transplant recipients. Limited anecdotal experience with sirolimus as a rescue agent in cases of refractory acute rejection, chronic allograft nephropathy, calcineurin inhibitor nephrotoxicity, and PTLD has been promising.

Most early reports in pediatric kidney transplantation appear to describe combinations of sirolimus with either tacrolimus or MMF; usually these are combined with prednisone, although efficacy has also been demonstrated with dual therapy (MMF and sirolimus) with complete steroid avoidance.

Corticosteroids

Corticosteroids remain an integral part of many immunosuppressive protocols despite their multifaceted toxicities. In children, retarded skeletal growth is the most noteworthy side effect of corticosteroids. Concerns remain about side effects, such as hypertension, obesity, diabetes mellitus, hyperlipidemia, osteopenia, and aseptic necrosis of bone (particularly the femoral heads). Cosmetic side effects, such as cushingoid faces and acne, are significant additional problems of chronic steroid use. Such side effects often tempt children and adolescent to stop taking their immunosuppressive drugs.

Steroid withdrawal attempts have led to improvements in blood pressure, lipid profiles, and growth. The benefits of steroid withdrawal have been overshadowed by high rates of acute rejection that occur in 25-70% of children. Studies using tacrolimus maintenance have shown safety in late steroid withdrawal, with low rates of acute rejection and no rebound early rejections. A steroid withdrawal trial using sirolimus had low rates of acute rejection but a high incidence of PTLD, which resulted in premature discontinuation of the study.

Complete steroid avoidance has emerged as an alternative strategy to prevent steroid-associated morbidities in children. The immunologic outcomes of these studies are the lower rates of acute rejection seen in these studies compared with standard of care protocols using steroids, suggesting that steroid avoidance might also have immunologic benefits. Building on such observations, investigators at a single center (Stanford University, Stanford, CA) initiated a steroid-avoidance protocol and demonstrated that complete steroid avoidance can be successfully achieved with excellent long-term outcomes at 8 yr, using tacrolimus in combination with MMF, and an extended 6 mo course of daclizumab. Other centers have had similar experience with complete steroid avoidance, using a similar protocol with tacrolimus and MMF and induction with either extended daclizumab or Thymoglobulin. The Stanford steroid-avoidance protocol has been replicated in a randomized multicenter U.S. trial (NIH/NIAID/CCTPT UO1 AI-55795) across 12 different pediatric kidney transplant programs in the United States, and this seminal trial confirms the safety of steroid avoidance in low-risk pediatric kidney transplant recipients with lower acute rejection rates, and significant benefits for growth, hypertension, and hyperlipidemia. Importantly, this study also confirmed the overall safety of steroid avoidance, with no adverse effects on generation of donor-specific antibody posttransplantation or histologic injury.

FLUID MANAGEMENT IN INFANTS AND SMALL CHILDREN

Maintenance of adequate blood flow to an adult-sized kidney in an infant or small child is crucial to avoid acute tubular necrosis (ATN) and graft loss from vascular thrombosis and primary nonfunction. The recipient aortic blood flow early after transplantation of an adult-size kidney more than doubles from pretransplantation aortic blood flow. The maximum blood flow that can be obtained in an adult-size kidney transplanted into a small child is approximately 65% of what was in the donor. Low blood flow states such as with hypovolemia or hypotension increase the risk for ATN, graft thrombosis, and graft nonfunction. In the postoperative period, patients are maintained on high fluid volumes.

Close attention is paid to blood pressure and hydration status in the operating room in an attempt to reduce the incidence of delayed graft function. Typically, a central venous catheter is inserted to monitor the central venous pressure throughout the operation. To achieve adequate renal perfusion, a central venous pressure of 12-15 cm H_2O should be achieved before removing the vascular clamps; a higher central venous pressure may be desirable in the case of a small infant receiving an adult-size kidney. Dopamine is usually started in the operating room at 2 to 3 μg/kg/min, increased if required, and continued for 24-48 hr postoperatively. It is used to facilitate diuresis and perhaps to affect renal vasodilation. The mean arterial blood pressure is kept >65-70 mm Hg by adequate hydration with a crystalloid solution and 5% albumin, and, if necessary, by using dopamine at higher doses. A blood transfusion with packed red blood cells may be required in very small recipients because the hemoglobin can drop as a result of sequestration of approximately 150-250 mL of blood in the transplanted kidney. Mannitol and/or furosemide may be given before removing the vascular clamps to increase the effective circulatory volume and facilitate diuresis. Mannitol can also act as a free-radical scavenger, and together with renal dose dopamine it is a critical factor for minimizing the ischemia–reperfusion injury in steroid-avoidance regimens. After the transplanted kidney starts to produce urine, volume replacement should be immediately started with normal saline.

Infants continue to receive aggressive fluid management by nasogastric or gastrostomy tube feedings of at least 2500 mL/m^2/day for ≥6 mo after transplant if the child is unable to take in sufficient volume. This aggressive fluid management showed 30 mL/min greater GFR in infants who received adult-size kidneys and who were maintained on this higher fluid requirement than infants who were not.

RENAL BIOPSY

Renal biopsy is the gold standard for diagnosis of acute allograft dysfunction. Protocol biopsies may improve graft outcome by detecting early pathology and help monitor drug nephrotoxicity. The largest serial analysis of protocol biopsies at implantation, 3, 6, 12, and 24 mo posttransplantation (the NIH SNSO1 trial, 2004-9) established that the prime risk factor for chronic histologic injury was discrepancy between recipient size and donor mass and time posttransplantation.

REJECTION

Hyperacute rejection occurs immediately when the kidney is transplanted and is caused by preformed antibodies against the donor HLA, ABO, or other antigens. Hyperacute rejection is rare. The only treatment is removal of the graft.

Acute cellular rejection needs to be identified and treated early. Diagnosis of acute rejection in the very young transplant recipient is often not straightforward. Because most small children receive adult-size kidneys, an elevation in serum creatinine may be a late sign of rejection as a result of the large renal reserve compared with the body mass. Thus, significant allograft dysfunction may be present with little or no increase in the serum creatinine level. One of the earliest and most sensitive signs of rejection is the development of hypertension along with low-grade fever. In children, any increase in serum creatinine, especially if it is accompanied by hypertension, should be considered a symptom of acute rejection until proved otherwise. Late diagnosis and treatment of rejection are associated with a higher incidence of resistant rejections and graft loss. Genomic studies in pediatric kidney transplantation have demonstrated molecular heterogeneity for different acute rejection episodes, not distinguishable by pathologic grading, but with a key established role for B cells as antigen-presenting cells for aggressive T-cell–mediated recalcitrant rejection.

Chronic rejection is the leading cause of graft loss and primarily results from immune and nonimmune injuries such as hypertension, diabetes, and hyperlipidemia. Children often have a gradual decline in their renal function and often have fixed proteinuria and hypertension. Despite initial excitement about the potential of MMF and sirolimus mitigating chronic graft injury, this has not translated readily into observable clinical benefits. Humoral immunity, relating the generation of posttransplant donor-specific anti-HLA antibodies, has been implicated in this injury; attention has also shifted to evaluating the impact of non-HLA antibodies after organ transplantation, as direct mediators of organ injury.

GRAFT SURVIVAL

Five yr graft survival is higher in living-donor recipients compared to grafts from deceased donors. The OPTN/SRTR 2007 annual report gives graft survival at 5 yr (2000-2005) for living-donor kidney transplant as 88.0% for recipients 1-5 yr of age, 84.6% for those 6-10 yr of age, and 74.4% for those 11-17 yr of age. Survival in deceased-donor recipients was 74.4% for those 1-5 yr of age, 72.1% for those 6-10 yr of age, and 63% for those 11-17 yr of age.

From the NAPRTCS data, graft survival rates of pediatric kidney transplants have improved since 1987 with 1 yr survival rates during 2003-2006 of 95.7% for living-donor transplants and 95%

for deceased-donor transplants. Children <10 yr of age have the best long-term graft and patient survival rates of all transplant recipients. Graft survival in adolescent patients is the lowest of all the age groups. It is well known that noncompliance is a difficult problem in this age group. Other risk factors for graft failure are race, previous transplant history, history of multiple blood transfusions, HLA-B matches, sex, and transplant year. Approximately 25% of pediatric kidney transplants are preemptive. Graft survival for living and deceased-donor kidneys is significantly better in the preemptive group compared to patients who are on dialysis first. The 3 most common causes of graft failure are chronic rejection of graft (34.9%), acute rejection of graft (13%), and vascular thrombosis (10.1%). Approximately 6.4% of patients had graft failure as a result of recurrence of primary disease (NAPRTCS 2007). The NAPRTCS 2003-2007 data showed the probability of the first rejection at 12 mo being 8.7% for the living donor and 17.7% for the deceased donor.

Graft survival is significantly worse in the presence of ATN in either donor group. ATN is defined by NAPRTCS as requiring the use of dialysis within the first transplant week. NAPRTCS 2008 data report a 5.1% delay in graft function in living-donor renal transplants compared to the ATN rate of 16.4% in children who received deceased-donor transplants.

COMPLICATIONS WITH IMMUNOSUPPRESSION INFECTIONS

Since the mid-1990s, the incidence of acute rejection has decreased but the incidence of infections after transplantation has been increasing.

Pneumonia and urinary tract infection are the most common post-transplant bacterial infections. Urinary tract infections can progress rapidly to urosepsis and may be confused with episodes of acute rejection. Trimethoprim-sulfamethoxazole is used for urinary tract infection antibiotic prophylaxis as well as *Pneumocystis carinii* pneumonia prophylaxis for at least the first 6 mo after transplant. Opportunistic infections associated with unusual organisms usually do not occur until after the first month after transplantation.

The **herpesviruses** (cytomegalovirus, herpesvirus, varicella-zoster virus, and EBV) pose a special problem in view of their common occurrence in children. Many young children have not yet been exposed to these viruses, and because they lack protective immunity, their predisposition to serious primary infection is high. The incidence of cytomegalovirus seropositivity is approximately 30% in children >5 yr of age and rises to approximately 60% in teenagers. Thus, the younger child is at a greater potential risk for serious infection when a cytomegalovirus-positive donor kidney is transplanted. About half the children are seronegative for EBV, and infection occurs in approximately 75% of these patients. Most EBV infections are clinically silent. PTLD in children may be related to EBV infection in the presence of vigorous immunosuppression. The incidence of these infections is higher in children who receive antibody induction therapy and after treatment of acute rejection. It has also been shown in children that subclinical replication of these viruses is much higher in regimens with maintenance steroids, versus protocols with complete steroid avoidance, and that even subclinical viral replication can have a detrimental effect on the incidence of acute rejection and graft function. Antiviral prophylaxis with ganciclovir and valganciclovir for 3-12 mo after transplantation, especially in the higher-risk groups (recipient-negative, donor-positive), have been effective in reducing the incidence of clinical cytomegalovirus disease. Serial surveillance for these viruses by quantitative polymerase chain reaction for viral load in the peripheral blood has also allowed educated minimization of immunosuppression with resultant reduction in viral burden.

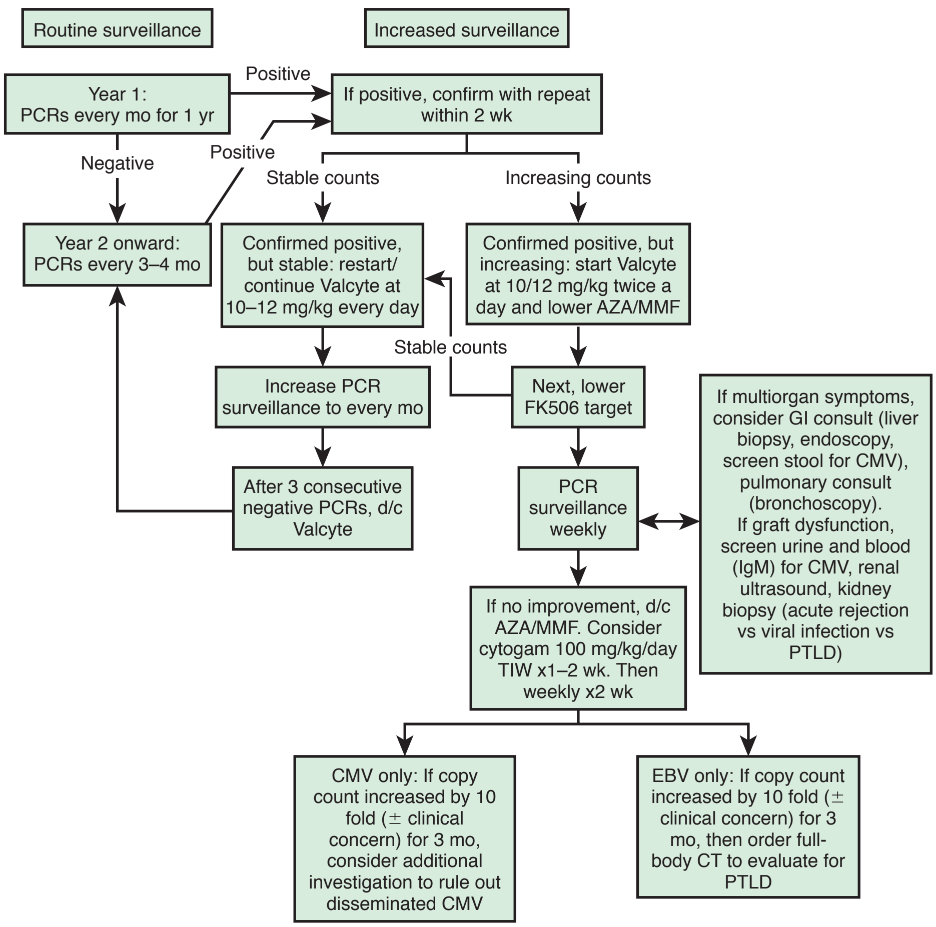

Figure 536-1 Surveillance for cytomegalovirus and Epstein-Barr virus infections after pediatric kidney transplantation.

Polyomavirus nephropathy is an important cause of allograft dysfunction; almost 30% of children have BK viruria, although allograft dysfunction is observed in lower numbers (~5%). The increased incidence of polyomavirus nephropathy is thought to be the result of more-potent immunosuppressive regimens. A renal biopsy, with identification of polyoma by immunoperoxidase staining, may be required to make the diagnosis with certainty. Reducing immunosuppression is the main form of therapy, and cidofovir and leflunomide are used as adjunctive therapies.

It is important to monitor for **PTLD** with routine examinations for lymphadenopathy, hepatosplenomegaly, and EBV screen. Figure 536-1 provides a schematic plan to monitor for EBV, cytomegalovirus, and PTLD.

Hypertension, hyperlipidemia, and posttransplant diabetes mellitus are other potential complications of immunosuppressant medications that need to be monitored for and treated when necessary.

Nonadherence with immunosuppressive medications is one of the most important and most elusive problems facing the medical team. At least half of the pediatric deceased-donor transplant recipients demonstrated significant medication nonadherence in the posttransplantation period by using as an assessment direct reporting to the medical team. This figure exceeded 60% in adolescents. Because direct reporting of nonadherence can significantly underestimate its true incidence, this analysis points out the potential magnitude of the problem. Nonadherence appears to be the principal cause of graft loss in 10-15% of all pediatric kidney transplant recipients; for patients with retransplants, this figure might exceed 25%. Risk factors that suggest an increased propensity toward medication nonadherence include female sex, adolescent age, family instability, insufficient emotional support, lower social economic class, and maladaptive behavior.

Although **growth** improves after transplantation, chronic steroid use does not allow a child to reach full potential height. The precise mechanism by which steroids impair skeletal growth is unknown. Steroids could reduce the release of growth hormone, reduce insulin growth factor activity, impair growth cartilage directly, decrease calcium absorption, or increase renal phosphate wasting. The use of recombinant human growth hormone in pediatric renal transplant recipients significantly improves growth velocity and standard deviation score (SDS). An allograft GFR of <60 mL/min/1.73 m^2 is associated with poor growth and low insulin growth factor levels; optimal growth occurs with a GFR >90 mL/min/1.73 m^2. Graft function is the most important factor after a high corticosteroid dosage in the genesis of posttransplantation growth failure. Steroid minimization and withdrawal protocols have demonstrated growth benefits, and the steroid-avoidance data in children show significant catch-up growth at 5 yr after transplantation. These factors have even greater weight than for age-matched, and gender-matched peers. It is thus likely that with a well-functioning kidney and no maintenance steroids, children might now be able to realize their full height potential.

LONG-TERM OUTCOME

With advances in transplant care and treatment modalities and with diligent attention to the pediatric patient's psychosocial, educational, vocational, and developmental rehabilitation, the social and emotional functioning of the child and the child's family appears to return to preillness levels within 1 yr of successful transplantation. Renal transplantation leads to improvement in linear growth in children. School function tests improve after renal transplantation. Most patients can reenter school and social activities after a short recovery time of 4-6 wk after surgery. A 3 yr follow-up shows that nearly 90% of children are in their appropriate school or job placement positions. Surveys of 10 year survivors of pediatric kidney transplants report that most patients consider their health to be good, and they engage in appropriate social, educational, and sexual activities while experiencing a very good to excellent quality of life.

Urologic Disorders in Infants and Children

PART XXIV

Chapter 537

Congenital Anomalies and Dysgenesis of the Kidneys

Jack S. Elder

EMBRYONIC DEVELOPMENT

The kidney is derived from interaction between the ureteral bud and the metanephric blastema. During the 5th wk of gestation, the ureteral bud arises from the mesonephric (wolffian) duct and penetrates the metanephric blastema, which is an area of undifferentiated mesenchyme on the nephrogenic ridge. The ureteral bud undergoes a series of approximately 15 generations of divisions and by the 20th wk of gestation forms the entire collecting system: the ureter, renal pelvis, calyces, papillary ducts, and collecting tubules. Signals from the mesenchymal cells induce ureteric bud formation from the wolffian duct as well as ureteric bud branching. Reciprocal signals from the ureteric bud and, later, from its branching tips induce mesenchymal cells to condense, proliferate, and convert into epithelial cells. Under the inductive influence of the ureteral bud, nephron differentiation begins during the 7th wk of gestation. By the 20th wk of gestation, when the collecting system is developed, approximately 30% of the nephrons are present. Nephrogenesis continues at a nearly exponential rate and is complete by the 36th wk of gestation. During nephrogenesis, the kidneys ascend to a lumbar site just below the adrenal glands. At least 16 signaling agents have been identified that regulate renal development. Defects in any of the signaling activities could cause a kidney not to form **(renal agenesis),** or to differentiate abnormally **(renal dysgenesis).** Dysgenesis of the kidney includes **aplasia**, **dysplasia**, **hypoplasia,** and certain forms of **renal cystic disease**.

The fetal kidneys play a minor role in the maintenance of fetal salt and water homeostasis. The rate of urine production increases throughout gestation; at term, volumes have been reported to be 50 mL/hr. The glomerular filtration rate is 25 mL/min/1.73 m^2 at term and triples by 3 mo postterm. The increase in glomerular filtration rate is caused by a reduction in intrarenal vascular resistance and redistribution of intrarenal blood flow to the cortex, where more nephrons are located.

RENAL AGENESIS

Renal agenesis, or absent kidney development, can occur secondary to a defect of the wolffian duct, ureteric bud, or metanephric blastema. Unilateral renal agenesis has an incidence of 1 in 450-1,000 births. Unilateral renal agenesis often is discovered during the course of an evaluation for other congenital anomalies (VACTERL [vertebral defects, imperforate anus, congenital heart disease, tracheoesophageal fistula, renal and limb defects] syndrome; e.g., see Chapter 344). Its incidence is increased in newborns with a single umbilical artery. In true agenesis, the ureter and the ipsilateral bladder hemitrigone are absent. The contralateral kidney undergoes compensatory hypertrophy, to some degree prenatally but primarily after birth. Approximately 15% of these children have contralateral vesicoureteral reflux, and most males have an ipsilateral absent vas deferens because the wolffian duct is absent. Because the wolffian and müllerian ducts are contiguous, müllerian abnormalities in girls also are common. The **Mayer-Rokitansky-Küster-Hauser** syndrome (1 in 4,000-1 in 10,000 female births) is a group of associated findings that may include vaginal aplasia, uterine maldevelopment, and normal ovaries. Two types are described—type I and type II. In type II, renal anomalies, for example, unilateral renal agenesis or a horseshoe kidney, are common, and skeletal anomalies are present in 10% (see Chapter 554).

Renal agenesis is distinguished from aplasia, in which a nubbin of nonfunctioning tissue is seen capping a normal or abnormal ureter. This distinction may be difficult but usually is clinically insignificant. Unilateral renal agenesis is diagnosed in some patients based on the finding of an absent kidney on ultrasonography or renal scintigraphy (renal scan). Some of these patients were born with a hypoplastic kidney or a multicystic dysplastic kidney that underwent complete cyst regression. Although the specific diagnosis is not critical, if the finding of an absent kidney is based on an ultrasonogram, a functional imaging study such as an MR urogram or renal scan should be performed because some of these patients have an ectopic kidney in the pelvis. If there is a normal contralateral kidney, long-term renal function usually remains normal.

Bilateral renal agenesis is incompatible with extrauterine life and produces the **Potter syndrome.** Death occurs shortly after birth from pulmonary hypoplasia. The newborn has a characteristic facial appearance, termed *Potter facies* (Fig. 537-1). The eyes are widely separated with epicanthic folds, the ears are low set, the nose is broad and compressed flat, the chin is receding, and there are limb anomalies. Bilateral renal agenesis should be suspected when maternal ultrasonography demonstrates **oligohydramnios,** nonvisualization of the bladder, and absent kidneys. The incidence of this disorder is 1 in 3,000 births, with a male predominance, and represents 20% of newborns with the Potter phenotype. Other common causes of neonatal renal failure associated with the Potter phenotype include cystic renal dysplasia and obstructive uropathy. Less-common causes are autosomal recessive polycystic kidney disease (infantile), renal hypoplasia, and medullary dysplasia. Neonates with bilateral renal agenesis die of pulmonary insufficiency from pulmonary hypoplasia rather than renal failure (see Chapter 101).

The term **familial renal adysplasia** describes families in which renal agenesis, renal dysplasia, multicystic kidney (dysplasia), or a combination, occurs in a single family. This disorder has an autosomal dominant inheritance pattern with a penetrance of 50-90% and variable expression. Because of this association, some clinicians advise screening 1st-degree relatives of persons who have renal agenesis or dysplasia, but this is not standard practice.

Whether persons with a solitary kidney should avoid contact sports such as football and karate is unresolved. The arguments favoring participation are that there are other solitary organs (spleen, liver, and brain) that do not preclude participation in contact sports, and there have been only a few reports of persons losing a kidney from sports injuries. The arguments against such participation are that the contralateral normal kidney is hypertrophic and not as well protected by the ribs, and a serious renal injury could have serious lifelong consequences. The American Academy of Pediatrics recommends an "individual assessment for contact, collision, and limited-contact sports."

RENAL DYSGENESIS: DYSPLASIA, HYPOPLASIA, AND CYSTIC ANOMALIES

Renal dysgenesis refers to maldevelopment of the kidney that affects its size, shape, or structure. The 3 principal types of dysgenesis are dysplastic, hypoplastic, and cystic. Although dysplasia always is accompanied by a decreased number of nephrons (hypoplasia), the converse is not true: Hypoplasia can occur in isolation. When both conditions are

Figure 537-1 Stillborn infant with renal agenesis exhibiting characteristic Potter facies.

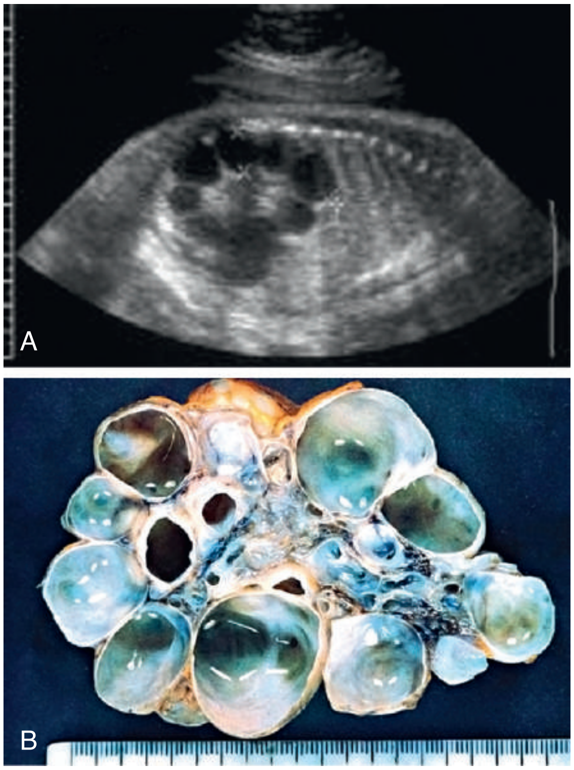

Figure 537-2 **A,** Prenatal sonogram demonstrating multicystic dysplastic kidney. **B,** Surgical specimen.

present, the term **hypodysplasia** is preferred. The term **dysplasia** is technically a histologic diagnosis and refers to focal, diffuse, or segmentally arranged primitive structures, specifically primitive ductal structures, resulting from abnormal metanephric differentiation. Nonrenal elements, such as cartilage, also may be present. The condition can affect all or only part of the kidney. If cysts are present, the condition is termed **cystic dysplasia.** If the entire kidney is dysplastic with a preponderance of cysts, the kidney is referred to as a **multicystic dysplastic kidney** (MCDK) (Fig. 537-2).

The pathogenesis of dysplasia is multifactorial. The "bud" theory proposes that if the ureteral bud arises in an abnormal location, such as an ectopic ureter, there is abnormal penetration and induction of the metanephric blastema, which causes abnormal kidney differentiation, resulting in dysplasia. Renal dysplasia also can occur with severe obstructive uropathy early in gestation, as with the most severe cases of posterior urethral valves or in an MCDK, in which a portion of the ureter is absent or atretic.

MCDK is a congenital condition in which the kidney is replaced by cysts and does not function; it can result from ureteral atresia. Kidney size is highly variable. The incidence is approximately 1 in 2,000. Some clinicians incorrectly use the terms *multicystic kidney* and *polycystic kidney* interchangeably. However, polycystic kidney disease is an inherited disorder that may be autosomal recessive or autosomal dominant and affects both kidneys (see Chapter 521). MCDK usually is unilateral and generally is not inherited. Bilateral MCDKs are incompatible with life.

MCDK is the most common cause of an abdominal mass in the newborn, but the vast majority are nonpalpable at birth. In most cases, it is discovered incidentally during prenatal sonography. In some patients, the cysts are identified prenatally, but the cysts regress in utero and no kidney is identified on imaging at birth. Contralateral hydronephrosis is present in 5-10% of patients. Sonography shows the characteristic appearance of a kidney replaced by multiple cysts of varying sizes that do not communicate, and no identifiable parenchyma is present. In the past, most cases were confirmed with a renal scan, which should demonstrate nonfunction. However, presently the diagnosis of MCDK is usually straightforward based on the renal ultrasound, and a scan generally is unnecessary. In some patients, usually boys, a small nonobstructing ureterocele is present in the bladder (see Chapter 540). Although 15% have contralateral vesicoureteral reflux, it is usually low grade, and obtaining a voiding cystourethrogram also is unnecessary, unless there is significant contralateral hydronephrosis or the child develops an upper urinary tract infection. Management is controversial. Complete cyst regression occurs in nearly half of MCDKs by age 7 yr. The risk of associated hypertension is 0.2-1.2%, and the risk of Wilms tumor arising from an MCDK is approximately 1 in 1,200. Because neoplasms arise from the stromal rather than the cystic component, even if the cysts regress completely, the likelihood that the kidney could develop a neoplasm is not altered.

Because of the occult nature of these potential problems, many clinicians advise annual follow-up with sonography and blood pressure measurement. The most important aspect of follow-up is being certain that the solitary kidney is functioning normally. If there is an abdominal mass, the cysts enlarge, the stromal core increases in size, or hypertension develops, nephrectomy is recommended. In lieu of follow-up screening, laparoscopic nephrectomy may be performed.

Renal hypoplasia refers to a small nondysplastic kidney that has fewer than the normal number of calyces and nephrons. The term encompasses a group of conditions with an abnormally small kidney and should be distinguished from aplasia, in which the kidney is rudimentary. If the condition is unilateral, the diagnosis usually is made incidentally during evaluation for another urinary tract problem or hypertension. Bilateral hypoplasia usually manifests with signs and symptoms of chronic renal failure and is a leading cause of end-stage renal disease during the 1st decade of life. A history of polyuria and polydipsia is common. Urinalysis results may be normal. In a rare form of bilateral hypoplasia called **oligomeganephronia,** the number of nephrons is markedly reduced and those present are markedly hypertrophied.

The **Ask-Upmark kidney,** also termed **segmental hypoplasia,** refers to small kidneys, usually weighing not more than 35 g, with 1 or more

Figure 537-3 **Crossed renal ectopia. Intravenous urography shows both renal collecting systems to the left of the spine.** Segmentation anomalies of the sacrum, which are subtle in this child, are one of the skeletal anomalies associated with renal ectopia. *(From Slovis T, editor:* Caffey's pediatric diagnostic imaging, *ed 11, vol 2, Philadelphia, 2008, Mosby, Fig. 145-23A, p. 2244.)*

deep grooves on the lateral convexity, underneath which the parenchyma consists of tubules resembling those in the thyroid gland. It is unclear whether the lesion is congenital or acquired. Most patients are 10 yr or older at diagnosis and have severe hypertension. Nephrectomy usually controls the hypertension.

ANOMALIES IN SHAPE AND POSITION

During renal development the kidneys normally ascend from the pelvis into their normal position behind the ribs. The normal process of ascent and rotation of the kidney may be incomplete, resulting in renal ectopia or nonrotation. The ectopic kidney may be in a pelvic, iliac, thoracic, or contralateral position. If the ectopia is bilateral, in 90% of persons the 2 kidneys fuse. The incidence of renal ectopia is approximately 1 in 900 (Fig. 537-3).

Renal fusion anomalies are more common. The lower poles of the kidneys can fuse in the midline, resulting in a horseshoe kidney (Fig. 537-4); the fused portion is termed the *isthmus* and may be thick functioning parenchyma or a thin fibrous strand. Horseshoe kidneys occur in 1 in 400-500 births but are seen in 7% of patients with Turner syndrome. Horseshoe kidney is one of the many renal anomalies that occur in 30% of patients with Turner syndrome (see Chapter 586). Wilms tumors are 4 times more common in children with horseshoe kidneys than in the general population. Stone disease and hydronephrosis secondary to ureteropelvic junction obstruction are other potential late complications. The incidence of MCDK affecting 1 of the 2 sides of a horseshoe kidney also appears to be increased. With crossed fused ectopia, 1 kidney crosses over to the other side and the parenchyma of the 2 kidneys is fused. Renal function usually is normal. In the most common finding, the left kidney may cross over and fuse with the lower pole of the right kidney. The insertion of the ureter to the bladder does not change, and the adrenal glands remain in their normal positions. The clinical significance of this anomaly is that if renal surgery is necessary, the blood supply is variable and can make partial nephrectomy more difficult.

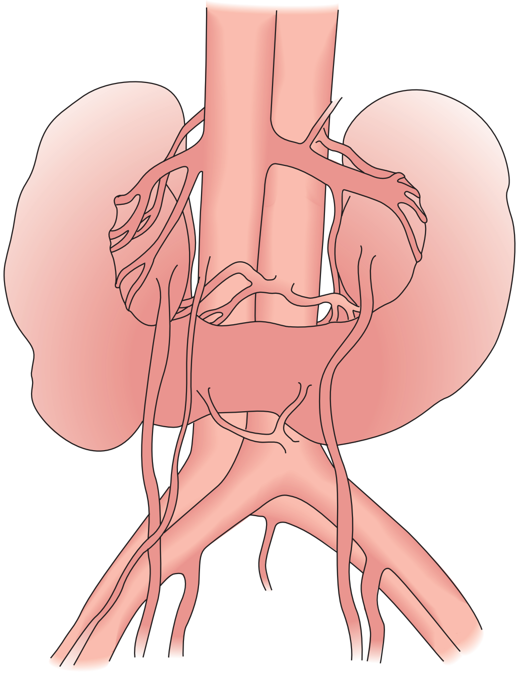

Figure 537-4 Horseshoe kidney.

ASSOCIATED PHYSICAL FINDINGS

Upper urinary tract anomalies are more common in children with certain physical findings. The incidence of renal anomalies is increased if there is a single umbilical artery and an abnormality of another organ system (congenital heart disease). External ear anomalies (particularly if the child has multiple congenital anomalies), imperforate anus, and scoliosis are associated with renal anomalies. Infants with these physical findings should undergo a renal sonogram.

Chapter 538

Urinary Tract Infections

Jack S. Elder

PREVALENCE AND ETIOLOGY

Urinary tract infections (UTIs) occur in 1% of boys and 1-3% of girls. The prevalence of UTIs varies with age. During the 1st yr of life, the male : female ratio is 2.8-5.4 : 1. Beyond 1-2 yr, there is a female preponderance, with a male : female ratio of 1 : 10. In boys, most UTIs occur during the 1st yr of life; UTIs are much more common in uncircumcised boys, especially in the 1st yr of life. In girls, the first UTI usually occurs by the age of 5 yr, with peaks during infancy and toilet training.

UTIs are caused primarily by colonic bacteria. In girls, 75-90% of all infections are caused by *Escherichia coli* (see Chapter 200), followed by *Klebsiella* spp. and *Proteus* spp. (see Chapter 109). Although *E. coli* is also the most common organism in males, some series report that in boys older than 1 yr of age, *Proteus* is as common a cause as *E. coli;* others report a preponderance of Gram-positive organisms in boys. *Staphylococcus saprophyticus* and enterococcus are pathogens in both

sexes. Adenovirus and other viral infections also can occur, especially as a cause of cystitis with gross hematuria.

UTIs have been considered a risk factor for the development of renal insufficiency or end-stage renal disease in children, although some have questioned the importance of UTI as an isolated risk factor, because only 2% of children with renal insufficiency report a history of UTI. This paradox may be secondary to better recognition of the risks of UTI and prompt diagnosis and therapy. Furthermore, many children receive antibiotics for fever without a specific diagnosis (e.g., treating a questionable otitis media) resulting in a partially treated UTI.

CLINICAL MANIFESTATIONS AND CLASSIFICATION

The 3 basic forms of UTI are **pyelonephritis**, **cystitis**, and **asymptomatic bacteriuria**. Focal pyelonephritis ("nephronia") and renal abscesses are less common.

Clinical Pyelonephritis

Clinical pyelonephritis is characterized by any or all of the following: abdominal, back, or flank pain; fever; malaise; nausea; vomiting; and, occasionally, diarrhea. *Fever may be the only manifestation*. Newborns can show nonspecific symptoms such as poor feeding, irritability, jaundice, and weight loss. Pyelonephritis is the most common serious bacterial infection in infants younger than 24 mo of age who have fever without an obvious focus (see Chapter 177). These symptoms are an indication that there is bacterial involvement of the upper urinary tract. Involvement of the renal parenchyma is termed *acute pyelonephritis,* whereas if there is no parenchymal involvement, the condition may be termed *pyelitis.* Acute pyelonephritis can result in renal injury, termed *pyelonephritic scarring.*

Acute lobar nephronia (acute lobar nephritis) is a renal mass caused by acute focal infection without liquefaction. It may be an early stage in the development of a renal abscess. Manifestations are identical to pyelonephritis; renal imaging demonstrates the abnormality (Fig. 538-1). *Renal abscess* can occur following a pyelonephritic infection caused by the usual uropathogens or may be secondary to hematogenous infection *(Staphylococcus aureus). Perinephric abscess* (Fig. 538-2) can occur secondary to contiguous infection in the perirenal area (e.g., vertebral osteomyelitis, psoas abscess) or pyelonephritis that dissects to the renal capsule.

Xanthogranulomatous pyelonephritis is a rare type of renal infection characterized by granulomatous inflammation with giant cells and foamy histiocytes. It can manifest clinically as a renal mass or an acute or chronic infection. Renal calculi, obstruction, and infection with *Proteus* spp. or *E. coli* contribute to the development of this lesion, which usually requires total or partial nephrectomy.

Cystitis

Cystitis indicates that there is bladder involvement; symptoms include dysuria, urgency, frequency, suprapubic pain, incontinence, and malodorous urine. Cystitis does not cause fever and does not result in renal injury. Malodorous urine is not specific for a UTI.

Acute hemorrhagic cystitis often is caused by *E. coli;* it also has been attributed to adenovirus types 11 and 21. Adenovirus cystitis is more common in boys; it is self-limiting, with hematuria lasting approximately 4 days.

Eosinophilic cystitis is a rare form of cystitis of obscure origin that occasionally is found in children. The usual symptoms are those of

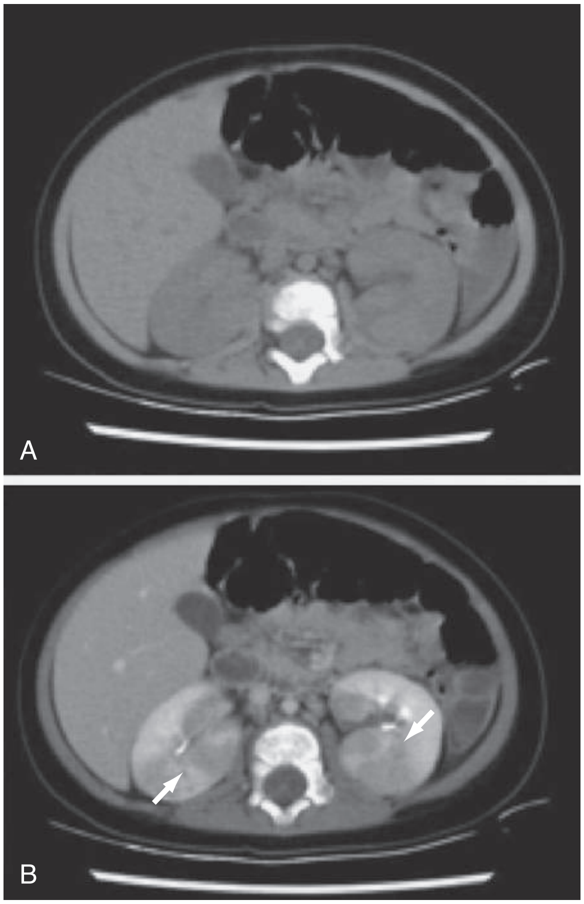

Figure 538-1 Characteristic precontrast **(A)** and contrast-enhanced **(B)** CT scans for an 8 mo old patient who had acute lobar nephronia and presented with severe bilateral nephromegaly but without a focal mass sonographically. No attenuation area is seen in the kidney before enhancement. *(From Cheng CH, Tsau YK, Lin TY: Effective duration of antimicrobial therapy for the treatment of acute lobar nephronia,* Pediatrics *117:e84–e89, 2006.)*

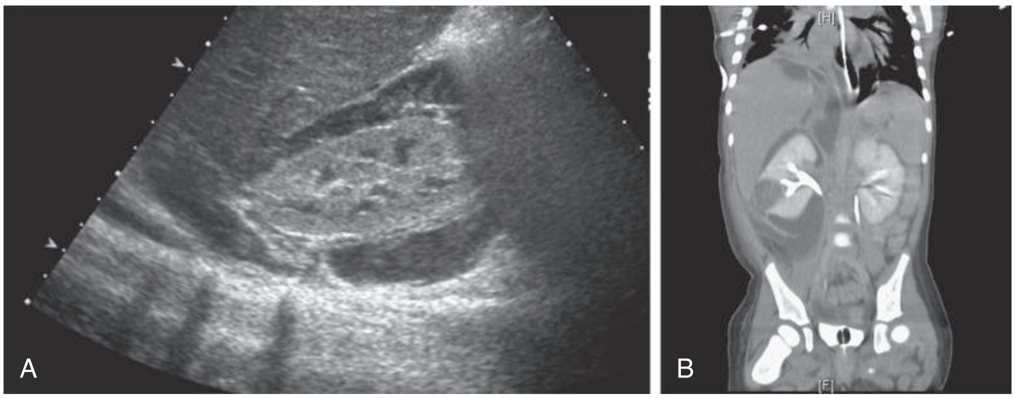

Figure 538-2 **A,** Renal sonogram, 19 mo old girl with perirenal abscess secondary to methicillin-resistant *Staphylococcus aureus.* **B,** CT scan demonstrates extensive perinephric and focal intrarenal abscess. Patient underwent incision and drainage.

cystitis with hematuria. On imaging, typically there are multiple solid bladder masses that consist histologically of inflammatory infiltrates with eosinophils. Ureteral dilation with hydronephrosis also is common. Children with eosinophilic cystitis may have been exposed to an allergen. Bladder biopsy often is necessary to exclude a neoplastic process. Treatment usually includes antihistamines and nonsteroidal antiinflammatory agents.

Interstitial cystitis is characterized by irritative voiding symptoms such as urgency, frequency, and dysuria, and bladder and pelvic pain relieved by voiding with a negative urine culture. The disorder is most likely to affect adolescent girls and is idiopathic. Diagnosis is made by cystoscopic observation of mucosal ulcers with bladder distention. Treatments have included bladder hydrodistention and laser ablation of ulcerated areas, but no treatment provides sustained relief.

Asymptomatic Bacteriuria

Asymptomatic bacteriuria refers to a condition in which there is a positive urine culture without any manifestations of infection. It is most common in girls. The incidence is <1% in preschool and school-age girls and is rare in boys. This condition is benign and does not cause renal injury, except in pregnant women, in whom asymptomatic bacteriuria, if left untreated, can result in a symptomatic UTI. Some girls are mistakenly identified as having asymptomatic bacteriuria, whereas they actually are experiencing day or night incontinence or perineal discomfort secondary to UTI; these patients should undergo antibiotic therapy.

PATHOGENESIS AND PATHOLOGY

Nearly all UTIs are ascending infections. The bacteria arise from the fecal flora, colonize the perineum, and enter the bladder via the urethra. In uncircumcised boys, the bacterial pathogens arise from the flora beneath the prepuce. In some cases, the bacteria causing cystitis ascend to the kidney to cause pyelonephritis. Rarely, renal infection occurs by hematogenous spread, as in endocarditis or in some neonates.

If bacteria ascend from the bladder to the kidney, acute pyelonephritis can occur. Normally the simple and compound papillae in the kidney have an antireflux mechanism that prevents urine in the renal pelvis from entering the collecting tubules. However, some compound papillae, typically in the upper and lower poles of the kidney, allow intrarenal reflux. Infected urine then stimulates an immunologic and inflammatory response. The result can cause renal injury and scarring (Figs. 538-3 and 538-4). Children of any age with a febrile UTI can have acute pyelonephritis and subsequent renal scarring, but the risk is highest in those younger than 2 yr of age.

Table 538-1 lists the host risk factors for UTI. Vesicoureteral reflux is discussed in Chapter 539. If there is grade III, IV, or V vesicoureteral reflux and a febrile UTI, 90% have evidence of acute pyelonephritis on renal scintigraphy or other imaging studies. In girls, UTIs often occur at the onset of toilet training because of bladder/bowel dysfunction that occurs at that age. The child is trying to retain urine to stay dry, yet the bladder may have uninhibited contractions forcing urine out. The result may be high-pressure, turbulent urine flow or incomplete bladder emptying, both of which increase the likelihood of bacteriuria. Bladder/bowel dysfunction can occur in the toilet-trained child who voids infrequently. Similar problems can arise in school-age children who refuse to use the school bathroom. Obstructive uropathy resulting in hydronephrosis increases the risk of UTI because of urinary stasis. Urethral catheterization for urine output monitoring or during a voiding cystourethrogram or nonsterile catheterization can infect the bladder with a pathogen. Constipation with fecal impaction can increase the risk of UTI because it can cause bladder dysfunction.

The pathogenesis of UTI is based in part on the presence of bacterial pili or fimbriae on the bacterial surface. There are 2 types of fimbriae, type I and type II. Type I fimbriae are found on most strains of *E. coli.* Because attachment to target cells can be blocked by D-mannose, these fimbriae are referred to as *mannose sensitive.* They have no role in pyelonephritis. The attachment of type II fimbriae is not inhibited by mannose, and these are known as *mannose resistant.* These fimbriae

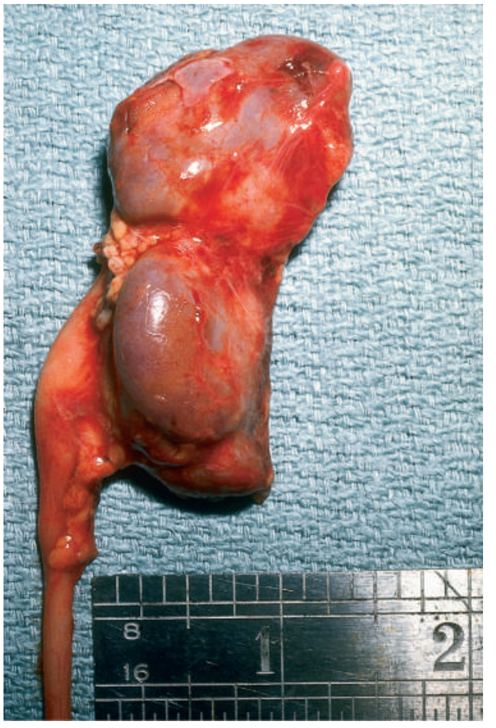

Figure 538-3 Scarred kidney from recurrent pyelonephritis.

Bubble bath?	

*Risk increased for clinical pyelonephritis, not cystitis.

are expressed by only certain strains of *E. coli*. The receptor for type II fimbriae is a glycosphingolipid that is present on both the uroepithelial cell membrane and red blood cells. The Gal 1-4 Gal oligosaccharide fraction is the specific receptor. Because these fimbriae can agglutinate by P blood group erythrocytes, they are known as P fimbriae. Bacteria with P fimbriae are more likely to cause pyelonephritis. Between 76% and 94% of pyelonephritogenic strains of *E. coli* have P fimbriae, compared with 19-23% of cystitis strains.

Other host factors for UTI include anatomic abnormalities precluding normal micturition, such as a labial adhesion. This lesion acts as a barrier and causes vaginal voiding. A neuropathic bladder can predispose to UTIs if there is incomplete bladder emptying and/or detrusor–sphincter dyssynergia. Sexual activity is associated with UTIs in girls, in part because of incomplete bladder emptying. From 4-7% of pregnant women have asymptomatic bacteriuria, which can develop into a symptomatic UTI. The incidence of UTI in infants who are breastfed is lower than in those fed with formula.

DIAGNOSIS

UTI may be suspected based on symptoms or findings on urinalysis, or both; *a urine culture is necessary for confirmation and appropriate therapy*. There are several ways to obtain a urine sample; some are more accurate than others. In toilet-trained children, a midstream urine sample usually is satisfactory; the introitus should be cleaned before obtaining the specimen. In uncircumcised boys, the prepuce must be retracted; if the prepuce is not retractable, a voided sample may be unreliable and contaminated with skin flora. According to the 2011 American Academy of Pediatrics (AAP) Clinical Guideline for children 2-24 mo, in children who are not toilet trained, a catheterized or suprapubic aspirate urine sample should be obtained. Alternatively, the application of an adhesive, sealed, sterile collection bag after disinfection of the skin of the genitals can be useful only if the culture is negative or if a single uropathogen is identified. However, a positive culture can result from skin contamination, particularly in girls and uncircumcised boys. If treatment is planned immediately after obtaining the urine culture, a bagged specimen should not be the method because of a high rate of contamination, often with mixed organisms. A suprapubic aspirate generally is unnecessary.

Nitrites and leukocyte esterase usually are positive in infected urine. Microscopic hematuria is common in acute cystitis, but microhematuria alone does not suggest UTI. White blood cell casts in the urinary sediment suggest renal involvement, but in practice these are rarely seen. If the child is asymptomatic and the urinalysis result is normal, it is unlikely that there is a UTI. However, if the child is symptomatic, a UTI is possible, even if the urinalysis result is negative (Table 538-2).

Pyuria (leukocytes on urine microscopy) suggests infection, but infection can occur in the absence of pyuria; this finding is more confirmatory than diagnostic. Conversely, pyuria can be present without UTI. Figure 538-3 shows the predictive value of leukocyte esterase, nitrites, and leukocytes.

Sterile pyuria (positive leukocytes, negative culture) may occur in partially treated bacterial UTIs, viral infections, renal tuberculosis, renal abscess, UTI in the presence of urinary obstruction, urethritis as a consequence of a sexually transmitted infection (see Chapter 120), inflammation near the ureter or bladder (appendicitis, Crohn disease), or interstitial nephritis (eosinophils). Prompt plating of the urine sample for culture is important, because if the urine sits at room temperature for more than 60 min, overgrowth of a minor contaminant can suggest a UTI when the urine might not be infected. Refrigeration is a reliable method of storing the urine until it can be cultured.

If the culture shows >50,000 colonies of a single pathogen (suprapubic or catheter sample), or if there are 10,000 colonies and the child is symptomatic, the child is considered to have a UTI. In a bag sample, if the urinalysis result is positive, the patient is symptomatic, and there is a single organism cultured with a colony count >100,000, there is a presumed UTI. If any of these criteria are not met, confirmation of infection with a catheterized sample is recommended.

With acute renal infection, leukocytosis, neutrophilia, and elevated serum erythrocyte sedimentation rate, procalcitonin, and C-reactive protein are common. However these are all nonspecific markers of inflammation, and their elevation does not prove that the child has acute pyelonephritis. With a renal abscess, the white blood cell count is markedly elevated to >20,000-25,000/mm^3. An elevated serum procalcitonin level is associated with pyelonephritis and a high risk of renal scarring. Because sepsis is common in pyelonephritis, particularly in infants and in any child with obstructive uropathy, blood cultures should be drawn before starting antibiotics if possible.

According to the 2011 AAP Guidelines for children 2-24 mo, risk factors for girls include white race, age younger than 12 mo, temperature >39°C (102.2°F), fever for longer than 2 days, and absence of another source of infection. Risk factors for boys include nonblack race, temperature >39°C (102.2°F), fever for longer than 24 hr, and absence of another source of infection. Atypical features include failure to respond within 48 hr of appropriate antibiotics, poor urine flow, an abdominal flank or suprapubic mass, non–*E. coli* pathogen, urosepsis, and an elevated creatinine level.

TREATMENT

Acute cystitis should be treated promptly to prevent possible progression to pyelonephritis. If the symptoms are severe, presumptive treatment is started pending results of the culture. If the symptoms are mild or the diagnosis is doubtful, treatment can be delayed until the results of culture are known, and the culture can be repeated if the results are uncertain. If treatment is initiated before the results of a culture and sensitivities are available, a 3- to 5-day course of therapy with trimethoprim-sulfamethoxazole (TMP-SMX) or trimethoprim is effective against many strains of *E. coli*. Nitrofurantoin (5-7 mg/kg/24 hr in 3-4 divided doses) also is effective and has the advantage of being active against *Klebsiella* and *Enterobacter* organisms. Amoxicillin (50 mg/kg/24 hr) also is effective as initial treatment but has a high rate of bacterial resistance.

In acute febrile infections suggesting **clinical pyelonephritis,** a 7-14 day course of broad-spectrum antibiotics capable of reaching significant tissue levels is preferable. Children who are dehydrated, are vomiting, are unable to drink fluids, are 1 mo of age or younger, have complicated infection, or in whom urosepsis is a possibility should be admitted to the hospital for IV rehydration and IV antibiotic therapy. Parenteral treatment with ceftriaxone (50-75 mg/kg/24 hr, not to

exceed 2 g) or cefotaxime (100 mg/kg/24 hr), or ampicillin (100 mg/kg/24 hr) with an aminoglycoside such as gentamicin (3-5 mg/kg/24 hr in 1-3 divided doses) is preferable. The potential ototoxicity and nephrotoxicity of aminoglycosides should be considered; serum creatinine should be obtained before initiating treatment, and daily trough gentamicin levels should be obtained during therapy. Treatment with aminoglycosides is particularly effective against *Pseudomonas* spp., and alkalinization of urine with sodium bicarbonate increases its effectiveness in the urinary tract.

Oral third-generation cephalosporins such as cefixime are as effective as parenteral ceftriaxone against a variety of Gram-negative organisms other than *Pseudomonas,* and these medications are considered by some authorities to be the treatment of choice for oral outpatient therapy. Nitrofurantoin should not be used routinely in children with a febrile UTI because it does not achieve significant renal tissue levels. The oral fluoroquinolone ciprofloxacin is an alternative agent for resistant microorganisms, particularly *Pseudomonas,* in patients older than age 17 yr. It also has been used on occasion for short-course therapy in younger children with *Pseudomonas* UTI. Levofloxacin is an alternative quinolone with a good safety profile in children. However, the clinical use of fluoroquinolones in children should be used with caution because of potential cartilage damage. In some children with a febrile UTI, intramuscular injection of a loading dose of ceftriaxone followed by oral therapy with a third-generation cephalosporin is effective. A urine culture 1 wk after the termination of treatment of a UTI ensures that the urine is sterile but is not routinely needed. A urine culture during treatment almost invariably is negative.

Children with a renal or perirenal abscess or with infection in obstructed urinary tracts can require surgical or percutaneous drainage in addition to antibiotic therapy and other supportive measures (see Fig. 538-2). Small abscesses may initially be treated without drainage.

In a child with recurrent UTIs, identification of predisposing factors is beneficial. Many school-age girls have **bladder–bowel dysfunction** (see Chapter 543); treatment of this condition often reduces the likelihood of recurrent UTI. Some children with UTIs void infrequently, and many also have severe constipation (see Chapters 306 and 332). Behavioral modification, with treatment of constipation as described in Chapter 543, often is effective. Antimicrobial prophylaxis using trimethoprim or nitrofurantoin at 30% of the normal therapeutic dose once a day is another approach to this problem but is unnecessary in most children with recurrent UTIs in the absence of severe reflux. Prophylaxis with TMP-SMZ, amoxicillin, or cephalexin can also be effective, but the risk of breakthrough UTI may be higher because bacterial resistance may be induced. Urologic conditions for recurrent UTIs that might benefit from long-term prophylaxis include neuropathic bladder, urinary tract stasis and obstruction, severe vesicoureteral reflux (see Chapter 539), and urinary calculi. There is interest in probiotic therapy, which replaces pathologic urogenital flora, and cranberry juice, which prevents bacterial adhesion and biofilm formation, but these agents have not proved beneficial in preventing UTI in children.

The main consequences of chronic renal damage caused by pyelonephritis are arterial hypertension and end-stage renal insufficiency; when they are found they should be treated appropriately (see Chapters 445 and 535).

IMAGING STUDIES IN CHILDREN WITH A FEBRILE UTI

The goal of imaging studies in children with a UTI is to identify anatomic abnormalities that predispose to infection, determine whether there is active renal involvement, and to assess whether renal function is normal or at risk.

There are 2 *historical* approaches to imaging, the traditional "bottom-up" and the "top-down" approaches.

1. The "bottom-up" method was a renal sonogram plus voiding cystourethrogram; this approach will identify upper and lower urinary tract abnormalities, including vesicoureteral reflux, bladder–bowel dysfunction, and bladder abnormalities, such as a paraureteral diverticulum. It is unlikely to detect renal scarring unless it is significant (renal cortical irregularity, small kidney on renal ultrasound). A dimercaptosuccinic acid (DMSA) scan is necessary to provide the best assessment of renal scarring.
   In some centers, the voiding cystourethrogram (VCUG) is delayed for 2-6 wk to allow inflammation in the bladder to resolve; however, the incidence of reflux is identical, regardless of whether the VCUG is obtained acutely at the time of treatment of the UTI or after 6 wk. Obtaining the VCUG before the child is discharged from the hospital is appropriate and ensures that the evaluation is complete. If available, a radionuclide VCUG rather than a contrast VCUG can be used in girls; this technique causes less radiation exposure to the gonads than does the contrast study. However, the radioisotope VCUG does not provide anatomic definition of the bladder, allow precise grading of reflux, demonstrate a paraureteral diverticulum, or show whether reflux is occurring into a duplicated collecting system or an ectopic ureter. In boys, VCUG definition of the urethra is important to detect posterior urethral valves (see Chapter 504).
2. The "top-down" approach was intended to reduce the number of VCUG examinations. It begins with a DMSA renal scan, to identify areas of acute pyelonephritic involvement, termed **acute pyelonephritis** (Fig. 538-5). The DMSA scan in younger children generally requires sedation. This condition is characterized by fever, malaise, abdominal or flank pain, and occasionally nausea and vomiting, and is a significant risk factor for renal injury and scarring. On DMSA, involved areas of the kidney are photopenic and the kidney is enlarged. Of children with a febrile UTI, approximately 50% have a positive DMSA scan. Of those with a positive scan, approximately 50% develop renal scarring in the areas of acute pyelonephritis, and in the remainder with acutely positive scans, the renal appearance will normalize. In children with dilating grades of reflux (III, IV, V), 80-90% with a febrile UTI have a DMSA scan consistent with acute pyelonephritis. Children with grades I and II reflux and those without reflux can also develop acute pyelonephritis. In longitudinal studies of children with grades I and II reflux and acute pyelonephritis, the reflux usually resolves. If the DMSA scan is normal during a febrile UTI, no scarring will result from that particular infection. CT is another diagnostic tool that can image acute pyelonephritis, but clinical experience with DMSA is much greater, and CT scans have significant radiation. If the DMSA scan is positive, then a VCUG is performed (Fig. 538-6), because 90% of children with dilating reflux have a positive DMSA scan. If reflux is identified, treatment is based on the perceived long-term risk of the reflux to the child (see Chapter 539). One limitation to this approach is that many hospitals caring for children with a febrile UTI might not have facilities for performing a DMSA scan in children. In these cases, a renal sonogram should be performed, after which the clinician decides whether to send the child to a facility with

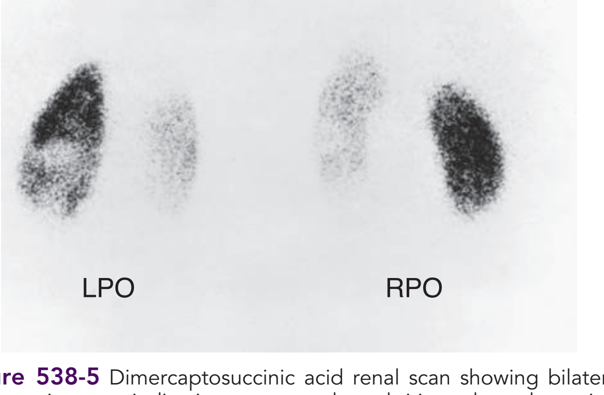

Figure 538-5 Dimercaptosuccinic acid renal scan showing bilateral photopenic areas indicating acute pyelonephritis and renal scarring. *LPO*, left posterior oblique; *RPO*, right posterior oblique.

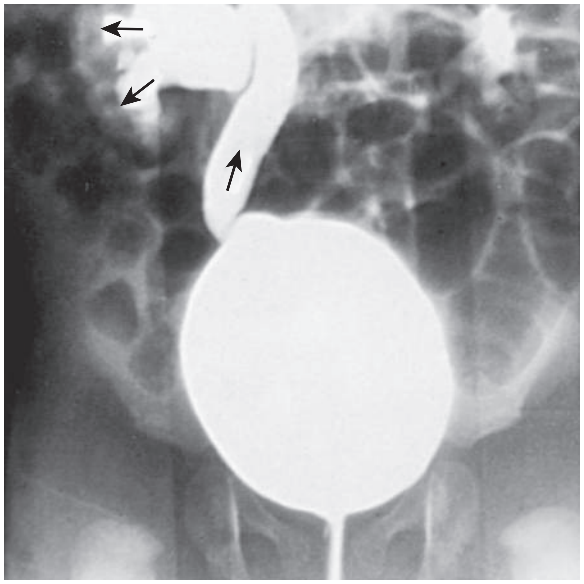

Figure 538-6 **Intrarenal reflux.** Voiding cystourethrogram in an infant boy with a past history of a urinary tract infection. Note the right vesicoureteral reflux with ureteral dilation, with opacification of the renal parenchyma representing intrarenal reflux.

DMSA capability or instead do a VCUG. In addition, if the DMSA scan is positive, then a follow-up scan is indicated 4-6 mo later to determine whether renal scarring occurred.

The AAP recommends that in a typical first-episode of UTI, initial imaging should be ultrasonography of the kidneys, ureters, and bladder. VCUG is indicated if the ultrasound study is abnormal, the patient has atypical features, or after a recurrent febrile UTI (Table 538-3).

In children with a history of cystitis, (dysuria, urgency, frequency, suprapubic pain), imaging is usually unnecessary. Instead, assessment and treatment of bladder and bowel dysfunction is important. If there are numerous lower UTIs, then a renal sonogram is appropriate, but a VCUG rarely adds useful information.

The AAP recommendation has resulted in a significant decrease in the number of VCUGs ordered. However, the pediatric urologic community has raised numerous concerns regarding the recommendations, and prospective studies will be necessary before determining whether they should be adopted. One consequence is that many primary care physicians have generalized these recommendations, which were intended for children *2-24 mo*, to *all* children.

Similarly, in 2007, the NICE (National Institute for Health and Clinical Excellence, UK) guidelines for diagnosis, management, and imaging after UTI were released (Table 538-4). These recommendations divided children into those younger than 6 mo, 6 mo-3 yr, and older than 3 yr of age. An initial VCUG is recommended only in children younger than age 6 mo. These recommendations are highly controversial

Table 538-3 Guideline Recommendations for Diagnostic Evaluation Following a Febrile Urinary Tract Infection in Infants

GUIDELINE	ULTRASONOGRAPHY	VCUG	LATE DMSA SCAN
National Institute for Health And Care Excellence (NICE)*	(see Table 538-4)

because the methodology was not based on evidence but on expert opinion. In addition, there was no retrospective or prospective assessment of the potential of this approach to identify significant uropathology. There is evidence that a significant number of children with uropathology would not have been identified under these guidelines.

PROPHYLAXIS OF RECURRENT URINARY TRACT INFECTION

See Chapter 539.

In children with a first episode of pyelonephritis in an otherwise anatomically normal urinary tract and no evidence of reflux, no antimicrobial prophylaxis is required in an attempt to prevent a recurrence or renal scarring.

Chapter 539

Vesicoureteral Reflux

Jack S. Elder

Vesicoureteral reflux (**VUR**) describes the retrograde flow of urine from the bladder to the ureter and kidney. The ureteral attachment to the bladder normally is oblique, between the bladder mucosa and detrusor muscle, creating a flap-valve mechanism that prevents VUR (Fig. 539-1). VUR occurs when the submucosal tunnel between the mucosa and detrusor muscle is short or absent. Affecting 1-2% of children, VUR usually is congenital and often is familial. VUR is present in approximately 30% of females who had a urinary tract infection and in 5-15% of infants with antenatal hydronephrosis.

VUR predisposes to kidney infection (pyelonephritis) by facilitating the transport of bacteria from the bladder to the upper urinary tract (see Chapter 538). The inflammatory reaction caused by pyelonephritis can result in renal injury or scarring, also termed **reflux-related renal injury** or **reflux nephropathy.** In children with a febrile ***urinary tract infection*** **(UTI)**, those with VUR are 3 times more likely to develop renal injury compared to those without VUR. Extensive renal scarring impairs renal function and can result in renin-mediated hypertension (see Chapter 445), renal insufficiency or end-stage renal disease (see Chapter 535), impaired somatic growth, and morbidity during pregnancy. Scarring associated with reflux may be present at birth or develop in the absence of infection.

In the past, reflux nephropathy accounted for as much as 15-20% of end-stage renal disease in children and young adults. With greater attention to the management of UTIs and a better understanding of VUR, end-stage renal disease secondary to reflux nephropathy is uncommon. Reflux nephropathy remains a common cause of hypertension in children. VUR in the absence of infection or elevated bladder pressure (e.g., neuropathic bladder, posterior urethral valves) rarely causes renal injury.

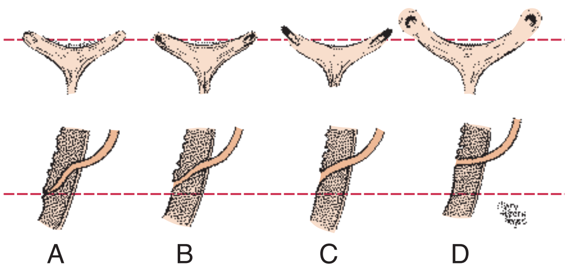

Figure 539-1 **Normal and abnormal configuration of the ureteral orifices.** Shown from *left* to *right*, progressive lateral displacement of the ureteral orifices and shortening of the intramural tunnels. *Top*, Endoscopic appearance. *Bottom*, Sagittal view through the intramural ureter.

CLASSIFICATION

VUR severity is graded using the International Reflux Study Classification of I-V and is based on the appearance of the urinary tract on a contrast ***voiding cystourethrogram*** **(VCUG)** (Figs. 539-2 and 539-3). The higher the VUR grade the greater the likelihood of renal injury. VUR severity is an indirect indication of the degree of abnormality of the ureterovesical junction.

VUR may be primary or secondary (Table 539-1). Bladder–bowel dysfunction can worsen preexisting VUR if there is a marginally competent ureterovesical junction. In the most severe cases, there is such massive VUR into the upper tracts that the bladder becomes

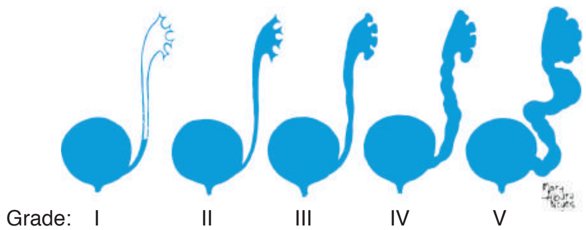

Figure 539-2 **Grading of vesicoureteral reflux.** Grade I: VUR into a nondilated ureter. Grade II: VUR into the upper collecting system without dilation. Grade III: VUR into dilated ureter and/or blunting of calyceal fornices. Grade IV: VUR into a grossly dilated ureter. Grade V: massive VUR, with significant ureteral dilation and tortuosity and loss of the papillary impression.

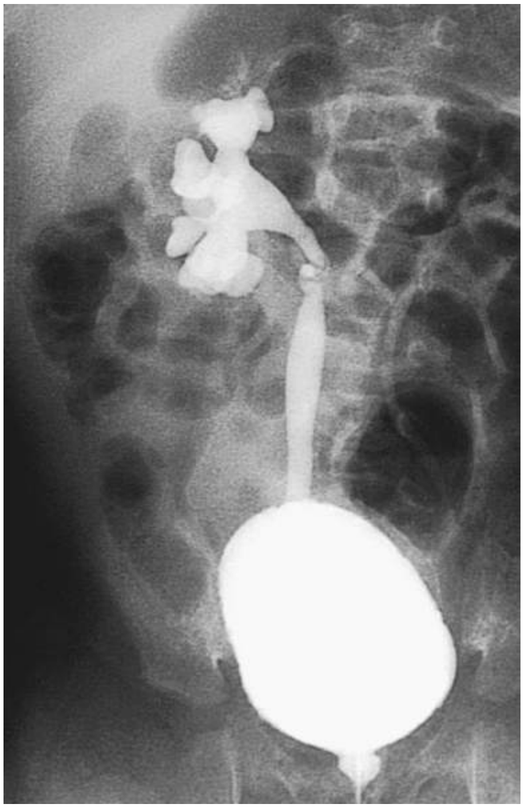

Figure 539-3 **Voiding cystourethrogram showing grade IV right vesicoureteral reflux.**

overdistended. This condition, the **megacystis-megaureter syndrome,** occurs primarily in boys and may be unilateral or bilateral (Fig. 539-4). Reimplantation of the ureters into the bladder to correct VUR corrects the condition.

Approximately 1 in 125 children have a **duplication** of the upper urinary tract, in which 2 ureters rather than 1 drain the kidney. Duplication may be partial or complete. In partial duplication, the ureters join above the bladder and there is 1 ureteral orifice. In complete duplication, the attachment of the lower pole ureter to the bladder is superior and lateral to the upper pole ureter. The valve-like mechanism for the lower pole ureter often is marginal, and VUR into the lower ureter occurs in as many as 50% of cases. VUR occurs into both the lower and upper systems in some persons (Fig. 539-5). With a duplication anomaly, some patients have an ectopic ureter, in which the upper pole ureter drains outside the bladder (see Chapters 540 and 543 and Figs. 543-6 and 543-7). If the ectopic ureter drains into the bladder neck, typically it is obstructed and refluxes. Duplication anomalies also are common in children with a ureterocele, which is a cystic swelling of the intramural portion of the distal ureter. These patients often have VUR into the associated lower pole ureter or the contralateral ureter. In addition, generally VUR is present when the ureter enters a bladder diverticulum (Fig. 539-6).

VUR is present at birth in 25% of children with **neuropathic bladder,** as occurs in myelomeningocele (see Chapter 591.4), sacral agenesis, and many cases of high imperforate anus. VUR is seen in 50% of boys with posterior urethral valves. VUR with increased intravesical pressure (as in detrusor–sphincter dyssynergia or bladder outlet obstruction) can result in renal injury because of increased intravesical pressure transmitted to the upper urinary tract, even in the absence of infection.

Primary VUR occurs in association with several congenital urinary tract abnormalities. Of children with a multicystic dysplastic kidney or renal agenesis (see Chapter 537), 15% have VUR into the contralateral kidney, and 10-15% of children with a ureteropelvic junction obstruction have VUR into either the hydronephrotic kidney or the contralateral kidney.

Table 539-1 Classification of Vesicoureteral Reflux

TYPE	CAUSE
Primary	Congenital incompetence of the valvular mechanism of the vesicoureteral junction
Primary associated with other malformations of the ureterovesical junction	Ureteral duplication Ureterocele with duplication Ureteral ectopia Paraureteral diverticula
Secondary to increased intravesical pressure	Neuropathic bladder Nonneuropathic bladder dysfunction Bladder outlet obstruction
Secondary to inflammatory processes	Severe bacterial cystitis Foreign bodies Vesical calculi Clinical cystitis
Secondary to surgical procedures involving the ureterovesical junction	Surgery

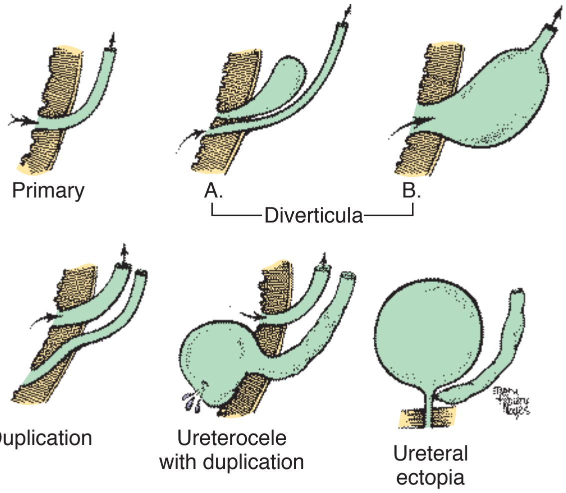

Figure 539-5 Various anatomic defects of the ureterovesical junction associated with vesicoureteral reflux.

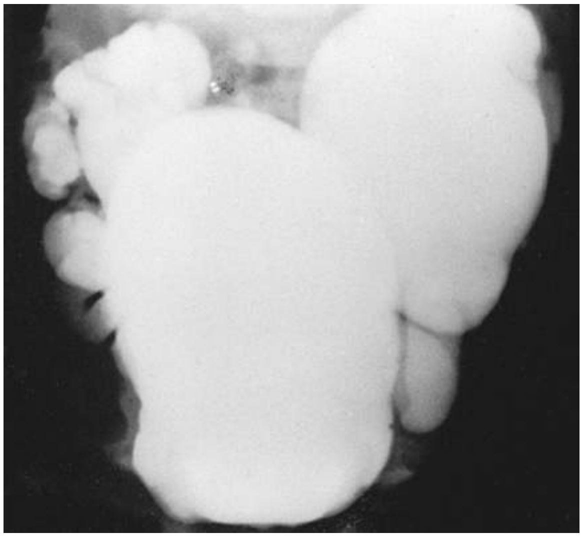

Figure 539-4 Voiding cystourethrogram in newborn boy with megacystis-megaureter syndrome. Note the massive ureteral dilation caused by high-grade vesicoureteral reflux. The bladder is very distended. There was no urethral obstruction or neuropathic dysfunction.

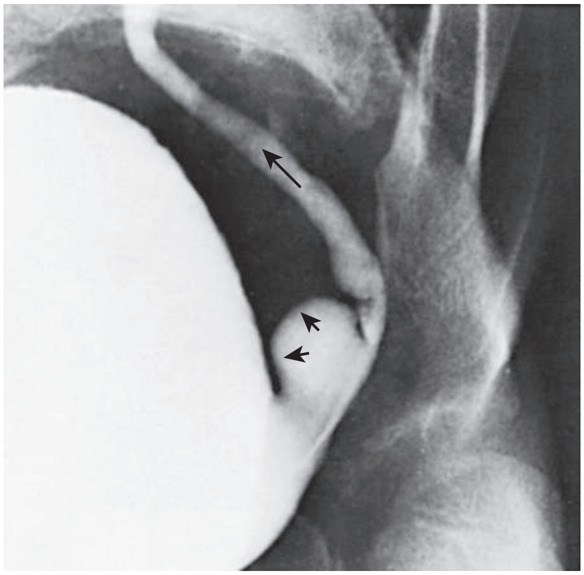

Figure 539-6 VUR and bladder diverticulum. The voiding cystourethrogram demonstrates left vesicoureteral reflux and a paraureteral diverticulum.

VUR (idiopathic) appears to be an autosomal dominant inherited trait with variable penetrance. Approximately 35% of siblings of children with VUR also have VUR, and VUR is found in nearly half of newborn siblings. The likelihood of a sibling having VUR is independent of the grade of VUR or sex of the index child. Approximately 12% of asymptomatic siblings with VUR have evidence of renal scarring. In addition, 50% of children born to women with a history of VUR also have VUR. In 2010 the American Urological Association Vesicoureteral Reflux Guidelines Panel stated that, in siblings of individuals with VUR, a VCUG or radionuclide cystogram is recommended if there is evidence of renal cortical abnormalities or renal size asymmetry on sonography, or if the sibling has a history of UTI. Otherwise, screening is optional. VUR may be suggested on a prenatal ultrasound, which demonstrates dilated renal calyces. Primary VUR is uncommon in African-Americans.

CLINICAL MANIFESTATIONS

VUR usually is discovered during evaluation for a UTI (see Chapter 538). Among these children, 80% are female, and the average age at diagnosis is 2-3 yr. In other children, a VCUG is performed during evaluation of bladder–bowel dysfunction, renal insufficiency, hypertension, or other suspected pathologic process of the urinary tract. Primary VUR also may be discovered during evaluation for antenatal hydronephrosis. In this select population, 80% of affected children are male, and the VUR grade usually is higher than in girls whose VUR is diagnosed following a UTI. The UTI may be symptomatic, an isolated febrile event, or more often both febrile and symptomatic (abdominal pain, dysuria, etc.). Bladder and bowel dysfunction (constipation) may be present in 50% of children with reflux and a UTI.

DIAGNOSIS

Diagnosis of VUR requires catheterization of the bladder, instillation of a solution containing iodinated contrast or a radiopharmaceutical, and radiologic imaging of the lower and upper urinary tract: a contrast VCUG or ***radionuclide cystogram***, respectively. The bladder and upper urinary tracts are imaged during bladder filling and voiding. VUR occurring during bladder filling is termed *low-pressure* VUR; VUR during voiding is termed *high-pressure* VUR. VUR in children with low-pressure VUR is significantly less likely to resolve spontaneously than in children who exhibit only high-pressure VUR. Radiation exposure during a radionuclide cystogram is significantly less than that from a contrast VCUG. However, the contrast VCUG provides more anatomic information, such as demonstration of a duplex collecting system, ectopic ureter, paraureteral (bladder) diverticulum, bladder outlet obstruction in boys, upper urinary tract stasis, and signs of voiding dysfunction, such as a "spinning top" urethra in girls. The VUR grading system is based on the appearance on contrast VCUG, and the grade reported is the maximum grade observed during the study. For follow-up evaluation, some prefer the radionuclide cystogram because of the lower radiation exposure (Fig. 539-7), although it is difficult to determine whether the VUR severity has changed.

Children undergoing cystography may be psychologically traumatized by the catheterization. Careful preparation by caregivers, use of Child Life individuals, or administration of oral or nasal midazolam (for sedation and amnesia) or propofol before the study can result in a less-distressing experience.

Indirect cystography is a technique of detecting VUR without catheterization that involves injecting an intravenous radiopharmaceutical that is excreted by the kidneys, waiting for it to be excreted into the bladder, and imaging the lower urinary tract while the patient voids. This technique detects only 75% of VUR cases. Another technique, which avoids radiation exposure, involves instilling sonographic contrast medium through a urethral catheter. The kidneys are imaged sonographically to determine whether any of the material refluxes. This technique is investigational.

After VUR is diagnosed, assessment of the upper urinary tract is important. The goal of upper tract imaging is to assess whether renal scarring and associated urinary tract anomalies are present. Renal imaging typically is performed with a renal sonogram or renal scintigraphy (Fig. 539-8; see Chapter 538).

The child should be evaluated for bladder–bowel dysfunction, including urgency, frequency, diurnal incontinence, infrequent voiding,

Figure 539-7 Radionuclide cystogram shows bilateral VUR.

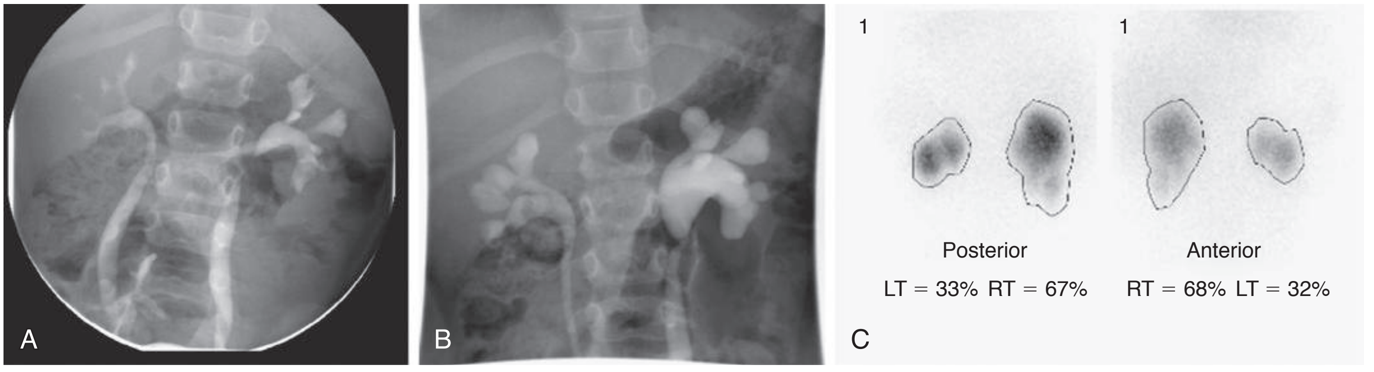

Figure 539-8 **A,** Voiding cystourethrogram (VCUG) in a 3 yr old girl with 2 febrile urinary tract infections shows bilateral grade III VUR. **B,** At 5 yr, repeat VCUG shows worsening VUR and calyceal clubbing, indicating renal scarring. **C,** At 11 yr, she has developed renin-mediated hypertension. Dimercaptosuccinic acid (DMSA) renal scan shows significant VUR-related renal scarring.

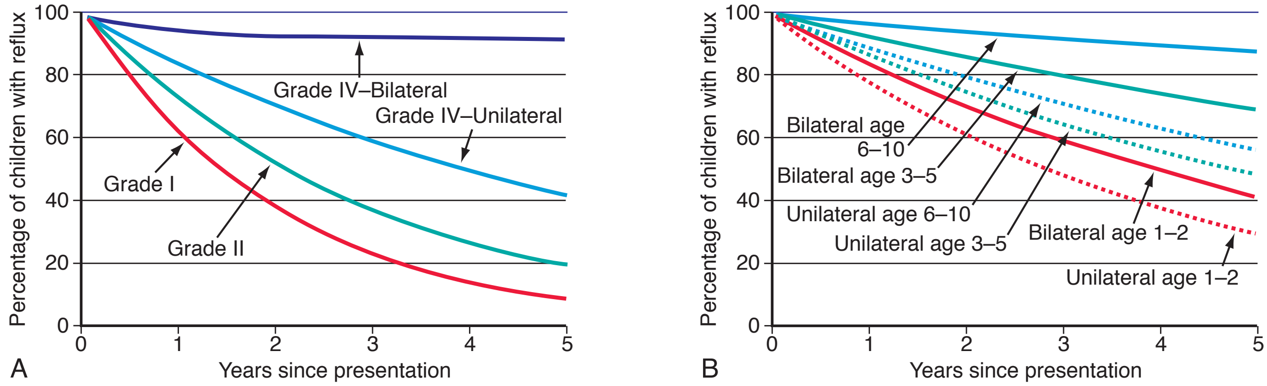

Figure 539-9 **A,** Percentage chance of VUR persistence, grades I, II, and IV, for 1-5 yr after presentation. **B,** Percentage chance of VUR persistence by age at presentation, grade III, for 1-5 yr after presentation. *(From Elder JS, Peters CA, Arant BS Jr, et al: Pediatric Vesicoureteral Reflux Guidelines Panel summary report on the management of primary vesicoureteral vesicoureteral reflux in children,* J Urol *157:1846–1851, 1997.)*

or a combination of these (see Chapter 543). Children with an overactive bladder often undergo a regimen of behavioral modification with timed voiding, and, on occasion, anticholinergic therapy.

After diagnosis, the child's height, weight, and blood pressure should be measured and monitored. If upper tract imaging shows renal scarring, a serum creatinine measurement should be obtained. The urine should be assessed for infection and proteinuria.

NATURAL HISTORY

The incidence of reflux-related renal scarring increases with VUR grade. With bladder growth and maturation, the VUR grade often resolves or improves. Lower grades of VUR are much more likely to resolve than are higher grades. For grades I and II VUR, the likelihood of resolution is similar regardless of age at diagnosis and whether it is unilateral or bilateral. For grade III, a younger age at diagnosis and unilateral VUR usually are associated with a higher rate of spontaneous resolution (Fig. 539-9). Bilateral grade IV VUR is much less likely to resolve than is unilateral grade IV VUR. Grade V VUR rarely resolves. The mean age at VUR resolution is 6 yr.

VUR does not usually cause renal injury in the absence of infection, but in situations with high-pressure VUR, as in children with posterior urethral valves, neuropathic bladder, and nonneurogenic neurogenic bladder (i.e., Hinman syndrome), sterile VUR can cause significant renal damage. Children with high-grade VUR who acquire a UTI are at significant risk for acute and recurrent pyelonephritis and new renal scarring (see Fig. 539-8).

TREATMENT

The goals of treatment are to prevent pyelonephritis, VUR-related renal injury, and other complications of VUR. Medical therapy is based on the principle that VUR often resolves over time and that if UTIs can be prevented, the morbidity or complications of VUR may be avoided without surgery. Medical therapy includes observation with behavioral modification or behavioral modification with antimicrobial prophylaxis in some patients. The basis for surgical therapy is that in selected children, ongoing VUR has caused or has significant potential for causing renal injury or other VUR-related complications, and that elimination of VUR minimizes the risk of these problems. Therapy for VUR should be individualized based on a particular patient's risk factors.

Observation

In children undergoing observation, therapeutic emphasis is directed to minimizing the risk of UTI by behavioral modification. These methods include timed voiding during the day, ensuring regular fecal elimination, increased fluid intake, periodic assessment of satisfactory bladder emptying, and prompt assessment and treatment of UTIs, particularly febrile UTIs. This approach is most appropriate for children with grades I and II VUR, and perhaps older children with persistent VUR and normal kidneys who have not experienced clinical pyelonephritis.

Antimicrobial Prophylaxis

In the past, based on clinical series demonstrating the effectiveness of antibiotic prophylaxis and the 1997 ***American Urological Association*** (**AUA**) Reflux Guidelines, daily prophylaxis was recommended as initial therapy for most children with VUR. Currently, many families express concern regarding the safety and benefit of prophylaxis. In addition, as a result of several prospective clinical trials, the benefit of prophylaxis has been questioned in children with VUR. The risk of recurrent UTI is highest in patients with grade III or IV reflux, those with bowel and bladder dysfunction, and those whose first reflux associated UTI was febrile rather than just symptomatic without fever. Antibiotic prophylaxis after a reflux associated UTI decreases the risk of recurrent UTI but increases the risk of developing resistant bacteria. In one study, antibiotic prophylaxis reduced the risk of new renal scars in children with grade III or IV reflux; while in another larger study antibiotic prophylaxis did not have an effect on the incidence of new renal scars in those with severe reflux (approximately 10% developed new scars regardless of prophylaxis).

Surgery

The purpose of surgical therapy is to minimize the risks of ongoing VUR and nonsurgical therapy (prophylaxis and follow-up testing). VUR can be corrected through a lower abdominal or inguinal incision (open), laparoscopically (with or without robotic assistance), or endoscopically with subureteral injection.

Open surgical management involves modifying the abnormal ureterovesical attachment to create a 4 : 1 to 5 : 1 ratio of intramural ureter length : ureteral diameter. The operation can be performed from either outside or inside the bladder. When VUR is associated with severe ureteral dilation (i.e., megaureter), the ureter must be tailored or narrowed to a more normal size to allow a smaller length : width ratio for the intramural tunnel, and a corner of the bladder is attached to the psoas tendon, forming a *psoas hitch*. Most children can be discharged 1-2 days following the surgical procedure. If the refluxing kidney is poorly functioning, nephrectomy or nephroureterectomy is indicated. Laparoscopic VUR correction and robotic-assisted laparoscopic ureteral reimplantation have being investigated and have been shown to have similar results to conventional open surgery in older children.

The success rate of conventional open ureteral reimplantation in children with primary VUR is >95-98% for grades I-IV, with 2% experiencing persistent VUR and 1% having ureteral obstruction that requires correction. The success rate is so high that many pediatric urologists do not perform a postoperative VCUG unless the child develops clinical pyelonephritis. For grade V VUR, the success rate is

approximately 80%. In lower grades of VUR, a failed reimplantation is most likely to occur in children with undiagnosed bladder-bowel dysfunction. In children with secondary VUR (posterior urethral valves, neuropathic bladder), the success rate is slightly lower than with primary VUR. The risk of pyelonephritis in children with grades III and IV VUR is significantly lower following open surgical correction compared with medical management. Surgical repair will not reverse renal scarring or cause improvement in renal function.

Endoscopic repair of VUR involves injection of a bulking agent through a cystoscope just beneath the ureteral orifice, creating an artificial flap-valve (Figs. 539-10 and 539-11). In 2001, the FDA approved the use of a biodegradable material, dextranomer microspheres suspended in hyaluronic acid (Deflux), for subureteral injection. The advantage of subureteral injection is that it is a noninvasive outpatient procedure (performed under general anesthesia) with no recovery time. The success rate is 70-80% and is highest for lower grades of VUR. If the first injection is unsuccessful, 1 or 2 repeat injections can be performed. The VUR recurrence rate is approximately 10%.

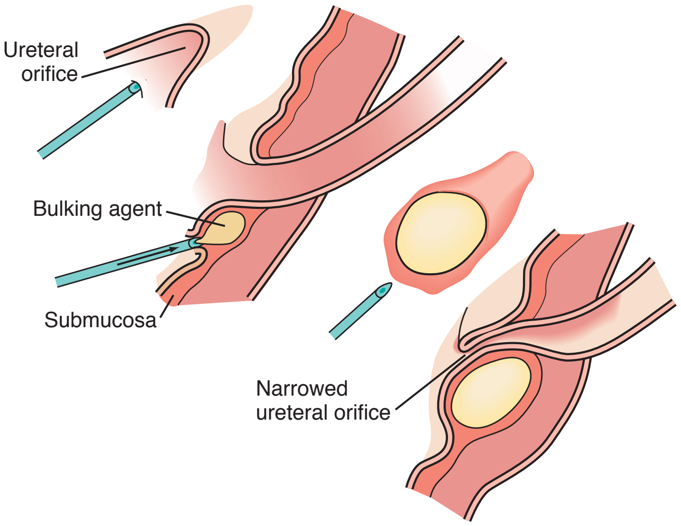

Figure 539-10 Endoscopic correction of VUR. Through a cystoscope, a needle is inserted into the submucosal plane deep to the ureteral orifice and bulking agent is injected, creating a flap-valve to prevent VUR. *(Adapted from Ortenberg J: Endoscopic treatment of vesicoureteral reflux in children,* Urol Clin North Am *25:151–156, 1998.)*

Current Vesicoureteral Reflux Guidelines

In 2010 the AUA provided updated evidence-based guidelines regarding VUR management, and in 2012 the European Association of Urology published expert opinion based guidelines. Both society recommendations were based on risk assessment of children with VUR.

The long-standing belief regarding the benefit of antibiotic prophylaxis in children with VUR has been questioned. Multiple randomized controlled prospective trials suggested that the risk of UTI in children with VUR is not reduced by prophylaxis. Most of the children in these trials had grades I-III VUR, and few younger than 1 yr old were studied. In contrast, the PRIVENT (Prevention of Recurrent Urinary Tract Infection in Children with Vesicoureteric Reflux and Normal Renal Tracts) trial from Australia showed significant benefit to prophylaxis in children with VUR. The Swedish VUR Trial in Children studied children younger than 2 yr of age with grades III and IV VUR; they compared antibiotic prophylaxis to observation and endoscopic injection therapy. Girls in the surveillance group had a significantly higher incidence of febrile UTI and new renal scarring compared to the other treatment groups. The largest randomized trial (RIVUR [Randomized Intervention for Children with Vesicoureteral Reflux]) enrolled more than 600 children and demonstrated a reduction in the recurrence rate of UTIs but no reduction of the occurrence of renal scarring with antibiotic prophylaxis.

Prophylaxis is recommended by the AUA in children at greatest risk for VUR-related renal injury (i.e., those younger than 1 yr of age). In addition, evaluation for ***bladder and bowel dysfunction*** is considered a standard part of initial and ongoing patient evaluation in children with VUR. Because children with bladder and bowel dysfunction and VUR are much more likely to have recurrent UTIs and renal scarring, prophylaxis is recommended for these children. In children with VUR who are being managed by surveillance, if a febrile UTI occurs, prophylaxis is recommended. The decision whether to recommend observation, medical therapy, or surgery is based on the risk of VUR to the patient, the likelihood of spontaneous resolution, and the parents' and patient's preferences, and the family should understand the risks and benefits of each treatment approach.

Another aspect of VUR management pertains to screening. VUR is known to be a familial disorder with autosomal dominant transmission with variable penetrance. The advantage of early VUR detection is to implement treatment before a potentially damaging episode of clinical pyelonephritis. In siblings of an index patient with VUR, optional management includes screening of asymptomatic siblings or offspring with a renal ultrasound or VCUG. The AUA recommends that a VCUG should be obtained if a screening ultrasound demonstrated a renal abnormality or if the sibling had a UTI.

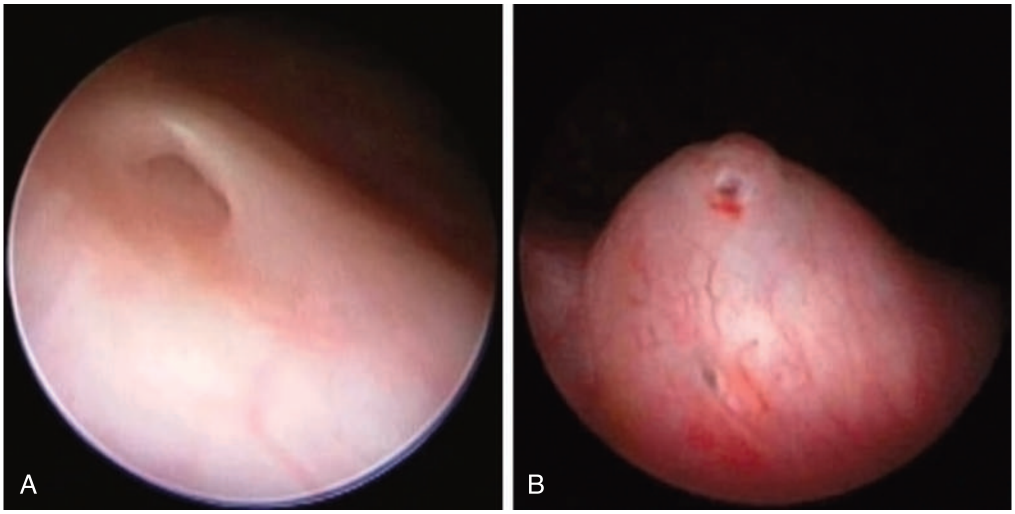

Figure 539-11 **A,** Endoscopic view of right vesicoureteral refluxing ureter. **B,** The same ureter after subureteral injection of dextranomer microspheres.

The AUA also determined that female newborns with renal pelvic dilation were significantly more likely than male newborns to have VUR. The AUA recommended that a VCUG should be performed in neonates with grade 3-4 antenatal hydronephrosis (moderate to severe pelvocaliceal dilation), hydroureter, or an abnormal bladder. In children with less-severe renal pelvic dilation, an observational approach without screening for VUR, with prompt treatment of any UTI, is appropriate. However, they also indicated that obtaining a VCUG is considered an appropriate option for neonates with lesser grades of hydronephrosis.

Chapter 540

Obstruction of the Urinary Tract

Jack S. Elder

Most childhood obstructive lesions are congenital, although urinary tract obstruction can be caused by trauma, neoplasia, calculi, inflammatory processes, or surgical procedures. Obstructive lesions occur at any level from the urethral meatus to the calyceal infundibula (Table 540-1). The pathophysiologic effects of obstruction depend on its level, the extent of involvement, the child's age at onset, and whether it is acute or chronic.

ETIOLOGY

Ureteral obstruction occurring early in fetal life results in renal dysplasia, ranging from multicystic kidney, which is associated with ureteral or pelvic atresia (see Fig. 537-2 in Chapter 537), to various degrees of histologic renal cortical dysplasia that are seen with less-severe obstruction. Chronic ureteral obstruction in late fetal life or after birth results in dilation of the ureter, renal pelvis, and calyces, with alterations of renal parenchyma ranging from minimal tubular changes to dilation of Bowman's space, glomerular fibrosis, and interstitial fibrosis. After birth, infections often complicate obstruction and can increase renal damage.

Prenatal screening with ultrasonography may detect antenatal hydronephrosis, which is graded by the trimester and the anterior-posterior diameter of the renal pelvis (Table 540-2); most are mild. Table 540-3 notes the eventual etiology.

CLINICAL MANIFESTATIONS

Obstruction of the urinary tract generally causes **hydronephrosis,** which typically is asymptomatic in its early phases. An obstructed kidney secondary to a **ureteropelvic junction (UPJ)** or **ureterovesical junction** obstruction can manifest as a unilateral mass or cause upper abdominal or flank pain on the affected side. Pyelonephritis can occur because of urinary stasis. An upper urinary tract stone can occur, causing abdominal and flank pain and hematuria. With bladder outlet obstruction, the urinary stream may be weak; urinary tract infection (UTI; see Chapter 538) is common. Many of these lesions are identified by antenatal ultrasonography; an abnormality involving the genitourinary tract is suspected in as many as 1 in 100 fetuses.

Obstructive renal insufficiency can manifest itself by failure to thrive, vomiting, diarrhea, or other nonspecific signs and symptoms. In older children, *infravesical obstruction* can be associated with overflow urinary incontinence or a poor urine stream. *Acute ureteral obstruction* causes flank or abdominal pain; there may be nausea and vomiting. *Chronic ureteral obstruction* can be silent or can cause vague abdominal or typical flank pain with increased fluid intake.

Table 540-1 Types and Causes of Urinary Tract Obstruction

LOCATION	CAUSE
Infundibula	Congenital Calculi Inflammatory (tuberculosis) Traumatic Postsurgical Neoplastic
Renal pelvis	Congenital (infundibulopelvic stenosis) Inflammatory (tuberculosis) Calculi Neoplasia (Wilms tumor, neuroblastoma)
Ureteropelvic junction	Congenital stenosis Calculi Neoplasia Inflammatory Postsurgical Traumatic
Ureter	Congenital obstructive megaureter Midureteral structure Ureteral ectopia Ureterocele Retrocaval ureter Ureteral fibroepithelial polyps Ureteral valves Calculi Postsurgical Extrinsic compression Neoplasia (neuroblastoma, lymphoma, and other retroperitoneal or pelvic tumors) Inflammatory (Crohn disease, chronic granulomatous disease) Hematoma, urinoma Lymphocele Retroperitoneal fibrosis
Bladder outlet and urethra	Neurogenic bladder dysfunction (functional obstruction) Posterior urethral valves Anterior urethral valves Diverticula Urethral strictures (congenital, traumatic, or iatrogenic) Urethral atresia Ectopic ureterocele Meatal stenosis (males) Calculi Foreign bodies Phimosis Extrinsic compression by tumors Urogenital sinus anomalies

Table 540-2 Definition of Antenatal Hydronephrosis by Anterior-Posterior Diameter

DEGREE OF ANTENATAL HYDRONEPHROSIS	SECOND TRIMESTER	THIRD TRIMESTER
Mild	4 to <7 mm	7 to <9 mm
Moderate	7 to ≤10 mm	9 to ≤15 mm
Severe	>10 mm	>15 mm

From Nguyen HT, Herndon CDA, Cooper C, et al: The society for fetal urology consensus statement on the evaluation and management of antenatal hydronephrosis. J Pediatr Urol *6:212–231, 2010, Table 2, p. 215.*

DIAGNOSIS

Urinary tract obstruction may be diagnosed prenatally by ultrasonography, which typically shows hydronephrosis and occasionally a distended bladder. More complete evaluation, including imaging studies, should be undertaken in these children in the neonatal period.

Urinary tract obstruction is often silent. In the newborn infant, a palpable abdominal mass most commonly is a hydronephrotic or multicystic dysplastic kidney. With posterior urethral valves, which is an infravesical obstructive lesion in boys, a walnut-sized mass representing the bladder is palpable just above the pubic symphysis. A **patent draining urachus** also can suggest urethral obstruction. **Urinary ascites** in the newborn usually is caused by renal or bladder urinary extravasation secondary to posterior urethral valves. Infection and sepsis may be the first indications of an obstructive lesion of the urinary tract. The combination of infection and obstruction poses a serious threat to infants and children and generally requires parenteral administration of antibiotics and drainage of the obstructed kidney. Renal ultrasonography should be performed in all children during the acute stage of an initial febrile UTI.

Imaging Studies

Renal Ultrasonography

Hydronephrosis is the most common characteristic of obstruction (Fig. 540-1). Upper urinary tract dilation is not diagnostic of obstruction and often persists after surgical correction of a significant obstructive lesion. Dilation can result from vesicoureteral reflux, or it may be a manifestation of abnormal development of the urinary tract, even when there is no obstruction. Renal length, degree of caliectasis and parenchymal thickness, and presence or absence of ureteral dilation should be assessed. Most pediatric urologists grade the severity of hydronephrosis from 1-4 using the Society for Fetal Urology grading scale (Table 540-4), whereas pediatric radiologists generally utilize the adjectives mild, moderate, and severe. The clinician should ascertain that the contralateral kidney is normal, and the bladder should be imaged to see whether the bladder wall is thickened, the lower ureter is dilated, and bladder emptying is complete. In acute or intermittent obstruction, the dilation of the collecting system may be minimal and ultrasonography may be misleading.

Table 540-3 The Etiology of Antenatal Hydronephrosis

ETIOLOGY	INCIDENCE
Transient hydronephrosis	41-88%
Ureteropelvic junction obstruction	10-30%
Vesicoureteral reflux	10-20%
Ureterovesical junction obstruction/megaureters	5-10%
Multicystic dysplastic kidney	4-6%
Posterior urethral valve/urethral atresia	1-2%
Ureterocele/ectopic ureter/duplex system	5-7%
Others: prune belly syndrome, cystic kidney disease, congenital ureteric strictures, and megalourethra	Uncommon

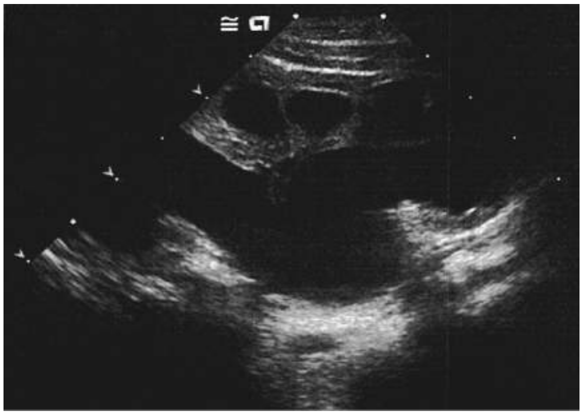

Figure 540-1 Ultrasonographic image of the kidney with marked pelvic and calyceal dilation (grade 4 hydronephrosis) in a newborn with ureteropelvic junction obstruction.

Voiding Cystourethrogram

In neonates and infants with congenital grade 3 or 4 hydronephrosis and in any child with ureteral dilation, a **contrast voiding cystourethrogram (VCUG)** should be obtained, because the dilation is secondary to vesicoureteral reflux in 15% of cases. In boys, the VCUG also is performed to rule out urethral obstruction, particularly in cases of suspected posterior urethral valves. In older children, the urinary flow rate can be measured noninvasively with a urinary flowmeter; decreased flow with a normal bladder contraction suggests infravesical obstruction (e.g., posterior urethral valves, urethral stricture). When the urethra cannot be catheterized to obtain a VCUG, the clinician should suspect a urethral stricture or an obstructive urethral lesion. Retrograde urethrography with contrast medium injected into the urethral meatus helps delineate the anatomy of the urethral obstruction.

Radioisotope Studies

Renal scintigraphy is used to assess renal anatomy and function. The 2 most commonly used radiopharmaceuticals are mercaptoacetyl triglycine (MAG-3) and technetium-99m-labeled dimercaptosuccinic acid. MAG-3, which is excreted by renal tubular secretion, is used to assess differential renal function, and when furosemide is administered, drainage also can be measured. An alternative to MAG-3 is diethylene tetrapentaacetic acid, which is cleared by glomerular filtration. The background activity of diethylene tetrapentaacetic acid is much higher than that of MAG-3. Dimercaptosuccinic acid is a renal cortical imaging agent and is used to assess differential renal function and to demonstrate whether renal scarring is present. It is used infrequently in children with obstructive uropathy.

In a MAG-3 diuretic renogram, a small dose of technetium-labeled MAG-3 is injected intravenously (Figs. 540-2 and 540-3). During the 1st 2-3 min, renal parenchymal uptake is analyzed and compared, allowing computation of differential renal function. Subsequently,

Table 540-4 Society for Fetal Urology Grading System for Hydronephrosis

GRADE OF HYDRONEPHROSIS	Renal Image: CENTRAL RENAL COMPLEX	Renal Image: RENAL PARENCHYMAL THICKNESS
0	Intact	Normal
1	Slight splitting	Normal
2	Evident splitting, complex confined within renal border	Normal
3	Wide splitting pelvis dilated outside renal border, calyces uniformly dilated	Normal
4	Further dilation of pelvis and calyces (calyces may appear convex)	Thin

After Maizels M, Mitchell B, Kass E, et al: Outcome of nonspecific hydronephrosis in the infant: a report from the registry of the Society for Fetal Urology, J Urol *152:2324–2327, 1994.*

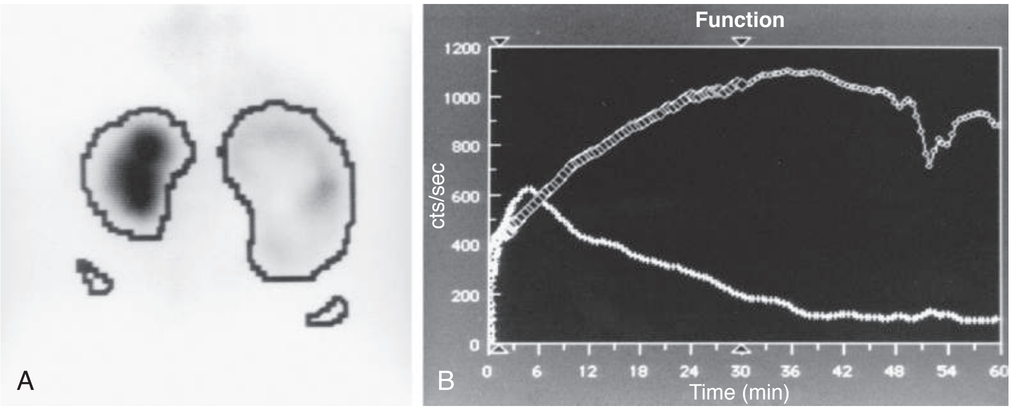

Figure 540-2 Same patient as in Figure 540-1. MAG-3 diuretic renogram of a 6 wk old patient. The right kidney is on the *right* side of the image. **A,** Differential renal function: left kidney 70%, right kidney 30%. **B,** After administration of furosemide, drainage from the left kidney was normal and drainage from the right kidney was slow, consistent with right ureteropelvic junction obstruction. Pyeloplasty was performed on the right kidney.

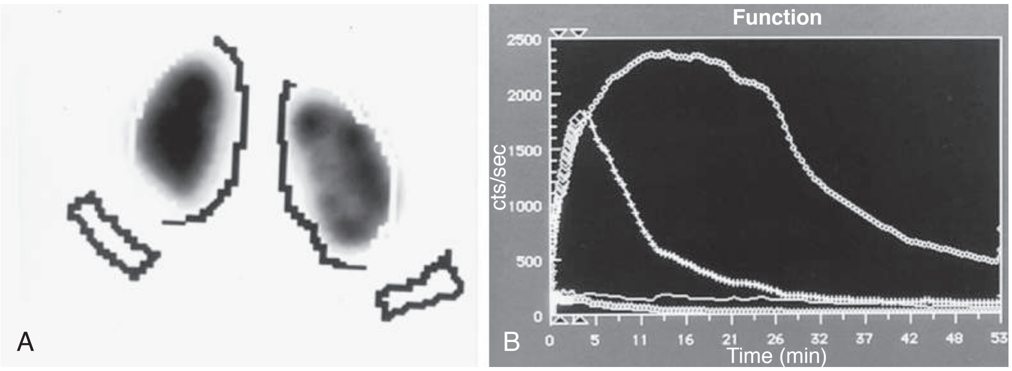

Figure 540-3 Same patient as in Figure 540-1. **A,** MAG-3 diuretic renogram at 14 mo of age shows equal function in the 2 kidneys. **B,** Prompt drainage after the administration of furosemide.

excretion is evaluated. After 20 min, furosemide 1 mg/kg is injected intravenously, and the rapidity and pattern of drainage from the kidneys to the bladder are analyzed. If no obstruction is present, half of the radionuclide should be cleared from the renal pelvis within 10-15 min, termed the half-time ($t_{1/2}$). If there is significant upper tract obstruction, the $t_{1/2}$ usually is longer than 20 min. A $t_{1/2}$ of 15-20 min is indeterminate. An elevated $t_{1/2}$ is suggestive but not diagnostic of obstruction. The images generated usually provide an accurate assessment of the site of obstruction. Numerous variables affect the outcome of the diuretic renogram. For example, newborn kidneys are functionally immature, and, in the 1st mo of life, normal kidneys might not demonstrate normal drainage after diuretic administration. Patient dehydration prolongs parenchymal transit and can blunt the diuretic response. Giving an insufficient dose of furosemide can result in slow drainage. If vesicoureteral reflux is present, continuous bladder drainage is mandatory to prevent the radionuclide from refluxing from the bladder into the dilated upper tract, which would prolong the washout phase..

The MAG-3 diuretic renogram is considered superior to the excretory urogram in infants and children with hydronephrosis, because bowel gas and immaturity of renal function often cause the intravenous pyelogram (IVP) images to be suboptimal. The diuretic renogram provides an objective assessment of the relative function of each kidney.

Excretory Urogram

Excretory urogram is rarely used in assessing the pediatric urinary tract, although it may be useful in selected cases with indeterminate upper urinary tract obstruction or a suspected duplication anomaly.

Magnetic Resonance Urography

MR urography is also used to evaluate suspected upper urinary tract pathology. The child is hydrated and given intravenous furosemide. Gadolinium-diethylene tetrapentaacetic acid is injected and routine T1-weighted and fat-suppressed fast spin-echo T2-weighted imaging is performed through the kidneys, ureters, and bladder. This study provides superb images of the pathology, and methodology permits assessment of differential renal function and drainage (Fig. 540-4). There is no radiation exposure; however, young children need sedation or anesthesia. It is used primarily when renal sonography and nuclear imaging fail to delineate complex pathology.

Computed Tomography

In children with a suspected ureteral calculus, noncontrast spiral CT of the abdomen and pelvis is a standard method of demonstrating whether a calculus is present, its location, and whether there is significant proximal hydronephrosis. This study is the initial study of choice in many of these patients. The disadvantage of CT is the significant radiation exposure, and it should be used only when the results will direct management decisions (see Chapter 718).

Ancillary Studies

In unusual cases, an **antegrade pyelogram** (insertion of a percutaneous nephrostomy tube and injection of contrast agent), can be performed to assess the anatomy of the upper urinary tract. This procedure usually requires general anesthesia. In addition, an **antegrade pressure-perfusion flow study** (Whitaker test) may be performed, in which fluid is infused at a measured rate, usually 10 mL/min. The pressures

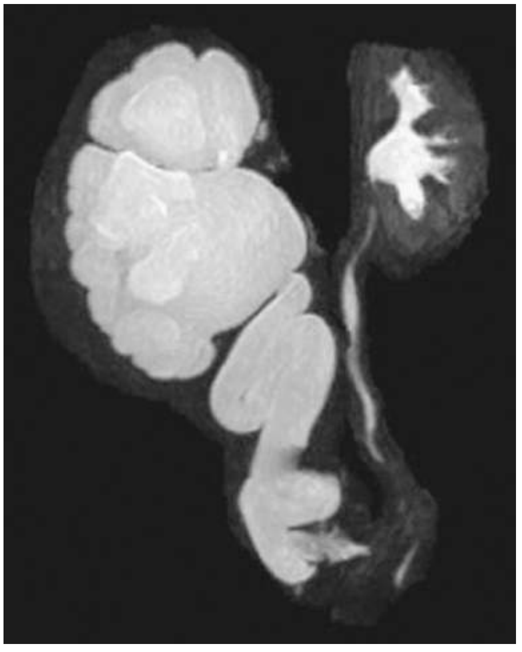

Figure 540-4 MR urogram in boy with distal ureterovesical obstruction.

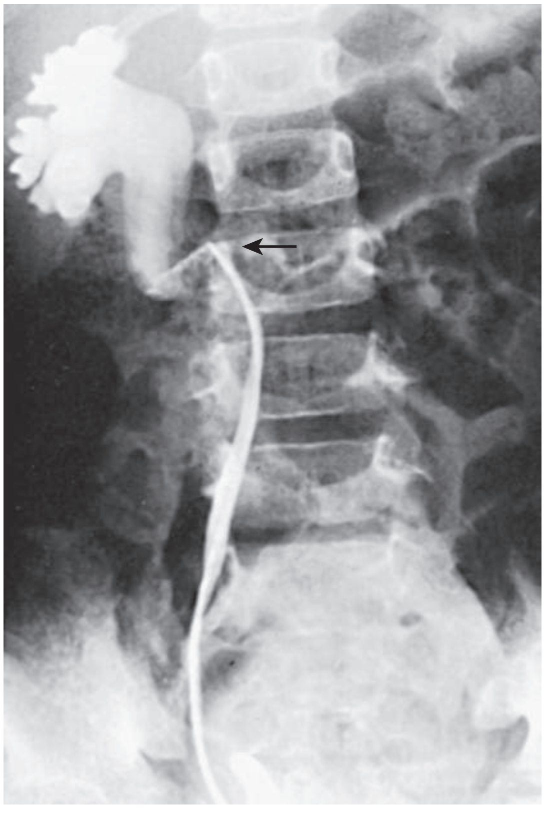

Figure 540-5 Retrograde pyelogram showing medial deviation of a dilated upper ureter to the level of the 3rd lumbar vertebra, characteristic of a retrocaval ureter.

in the renal pelvis and the bladder are monitored during this infusion, and pressure differences exceeding 20 cm H_2O suggest obstruction. In other cases, cystoscopy with retrograde pyelography provides excellent images of the upper urinary tract (Fig. 540-5).

SPECIFIC TYPES OF URINARY TRACT OBSTRUCTION AND THEIR TREATMENT

Hydrocalycosis

The term *hydrocalycosis* refers to a localized dilation of the calyx caused by obstruction of its infundibulum, termed *infundibular stenosis.* This condition can be developmental in origin or secondary to inflammatory processes, such as UTI. It usually is discovered during evaluation for pain or UTI. The diagnosis of infundibular stenosis is usually established by sonograph and CT scan or MR urography.

Ureteropelvic Junction Obstruction

UPJ obstruction is the most common obstructive lesion in childhood and usually is caused by intrinsic stenosis (see Figs. 540-1 to 540-3). An accessory artery to the lower pole of the kidney also can cause extrinsic obstruction. The typical appearance on ultrasonography is grade 3 or 4 hydronephrosis without a dilated ureter. UPJ obstruction most commonly manifests on antenatal sonography revealing fetal hydronephrosis; as a palpable renal mass in a newborn or infant; as abdominal, flank, or back pain; as a febrile UTI; or as hematuria after minimal trauma. Approximately 60% of cases occur on the left side, and the male : female ratio is 2 : 1. *UPJ obstruction is bilateral in only 10% of cases*. In kidneys with UPJ obstruction, renal function may be significantly impaired from pressure atrophy, but approximately half of affected kidneys have relatively normal glomerular function. The anomaly is corrected by performing a pyeloplasty, in which the stenotic segment is excised and the normal ureter and renal pelvis are reattached. Success rates are 91-98%. Pyeloplasty can be performed using laparoscopic techniques, often robotic-assisted using the da Vinci robot.

Lesser degrees of UPJ narrowing might cause mild hydronephrosis, which usually is nonobstructive, and typically these kidneys function normally. The spectrum of UPJ abnormalities has been referred to as *anomalous UPJ.* Another cause of mild hydronephrosis is fetal folds of the upper ureter, which also are nonobstructive.

The diagnosis can be difficult to establish in an asymptomatic infant in whom dilation of the renal pelvis is found incidentally in a prenatal ultrasonogram. After birth, the sonographic study is repeated to confirm the prenatal finding. A VCUG is necessary because 10-15% of patients have ipsilateral vesicoureteral reflux. Because neonatal oliguria can cause temporary decompression of a dilated renal pelvis, it is ideal to perform the first postnatal sonogram after the 3rd day of life. Delaying the sonogram may be impractical. If no dilation is found on the initial sonogram, a repeat study should be performed at 1 mo of age. If the kidney shows grade 1 or 2 hydronephrosis and the renal parenchyma appears normal, a period of observation usually is appropriate, with sequential renal ultrasonograms to monitor the severity of hydronephrosis, and the hydronephrosis usually disappears. **Antibiotic prophylaxis** is not indicated for children with mild hydronephrosis. If the hydronephrosis is grade 3 or 4, spontaneous resolution is less likely and obstruction is more likely to be present, particularly if the renal pelvic diameter is 3 cm. A diuretic renogram with MAG-3 is performed at 4-6 wk of age. If there is poor upper tract drainage or the differential renal function is poor, pyeloplasty is recommended. After pyeloplasty the differential renal function often improves, and improved drainage with furosemide stimulation is expected.

If the differential function on renography is normal, and drainage is satisfactory, the infant can be followed with serial ultrasonograms, even with grade 4 hydronephrosis. If the hydronephrosis remains severe with no improvement, a repeat diuretic renogram after 6-12 mo can help in the decision between continued observation and surgical repair. Prompt surgical repair is indicated in infants with an abdominal mass, bilateral severe hydronephrosis, a solitary kidney, or diminished function in the involved kidney. In unusual cases in which the differential renal function is <10% but the kidney definitely has some function, insertion of a percutaneous nephrostomy tube allows drainage of the hydronephrotic kidney for a few weeks to allow reassessment of renal function. In older children who present with symptoms, the diagnosis of UPJ obstruction usually is established by ultrasonography and diuretic renography.

The following entities should be considered in the **differential diagnosis:** megalycosis, a congenital nonobstructive dilation of the calyces without pelvic or ureteric dilation; vesicoureteral reflux with marked dilation and kinking of the ureter; midureteral or distal ureteral obstruction when the ureter is not well visualized on the urogram; and retrocaval ureter.

Midureteral Obstruction

Congenital ureteral stenosis or a ureteral valve in the midureter is rare. It is corrected by excision of the strictured segment and reanastomosis of the normal upper and lower ureteral segments. A **retrocaval ureter** is an anomaly in which the upper right ureter travels posterior to the inferior vena cava. In this anomaly, the vena cava can cause extrinsic compression and obstruction. An IVP or MR urogram shows the right ureter to be medially deviated at the level of the 3rd lumbar vertebra. The diagnosis may be confirmed by retrograde pyelography (see Fig. 540-5). Surgical treatment consists of transection of the upper ureter, moving it anterior to the vena cava, and reanastomosing the upper and lower segments. Repair is necessary only when obstruction is present. Retroperitoneal tumors, fibrosis caused by surgical procedures, inflammatory processes (as in chronic granulomatous disease), and radiation therapy can cause acquired midureteral obstruction.

Ectopic Ureter

A ureter that drains outside the bladder is referred to as an **ectopic ureter.** This anomaly is 3 times as common in girls as in boys and usually is detected prenatally. The ectopic ureter typically drains the upper pole of a duplex collecting system (2 ureters).

In girls, approximately 35% of these ureters enter the urethra at the bladder neck, 35% enter the urethrovaginal septum, 25% enter the vagina, and a few drain into the cervix, uterus, Gartner duct, or a urethral diverticulum. Often the terminal aspect of the ureter is narrowed, causing hydroureteronephrosis. With the exception of the ectopic ureter entering the bladder neck, in girls an ectopic ureter causes continuous urinary incontinence from the affected renal moiety. UTI is common because of urinary stasis.

In boys, ectopic ureters enter the posterior urethra (above the external sphincter) in 47%, the prostatic utricle in 10%, the seminal vesicle in 33%, the ejaculatory duct in 5%, and the vas deferens in 5%. Consequently, in boys, an ectopic ureter does not cause incontinence, and most patients present with a UTI or epididymitis.

Evaluation includes a renal sonogram, VCUG, and renal scan, which demonstrates whether the affected segment has significant function. The sonogram shows the affected hydronephrotic kidney or dilated upper pole and ureter down to the bladder (Fig. 540-6). If the ectopic ureter drains into the bladder neck (female), a VCUG usually shows reflux into the ureter. Otherwise, there is no reflux into the ectopic ureter, but there may be reflux into the ipsilateral lower pole ureter or contralateral collecting system.

Treatment depends on the status of the renal unit drained by the ectopic ureter. If there is satisfactory function, ureteral reimplantation into the bladder or ureteroureterostomy (anastomosing the ectopic upper pole ureter into the normally inserting lower pole ureter) is indicated. If function is poor, partial or total nephrectomy is indicated. In many centers this procedure is done laparoscopically and often with robotic assistance using the da Vinci robot.

Ureterocele

A ureterocele is a cystic dilation of the terminal ureter and is obstructive because of a pinpoint ureteral orifice. Ureteroceles are much more common in girls than in boys. Affected children usually are discovered by prenatal ultrasonography, but some present with a febrile UTI. Ureteroceles may be ectopic, in which case the cystic swelling extends through the bladder neck into the urethra, or orthotopic, in which case the ureterocele is entirely within the bladder. Both orthotopic and ectopic ureteroceles can be bilateral.

In girls, ureteroceles nearly always are associated with ureteral duplication (Fig. 540-7), whereas in 50% of affected boys there is only 1

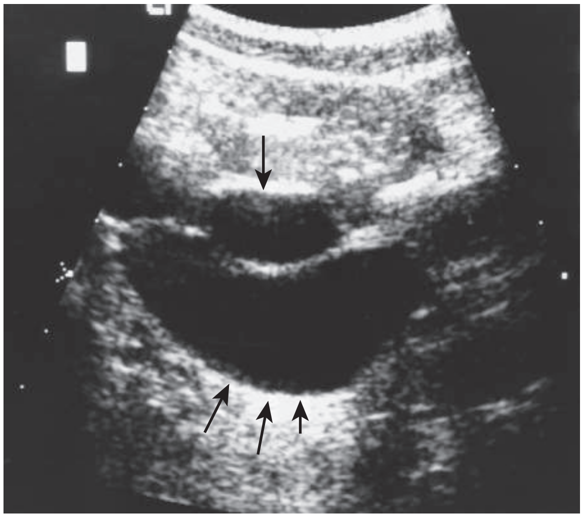

Figure 540-6 Ultrasonographic image of the right dilated ureter *(bottom arrows)* extending behind and caudal to a nearly empty bladder *(top arrow)* in a girl with urinary incontinence and ectopic ureter draining into the vagina.

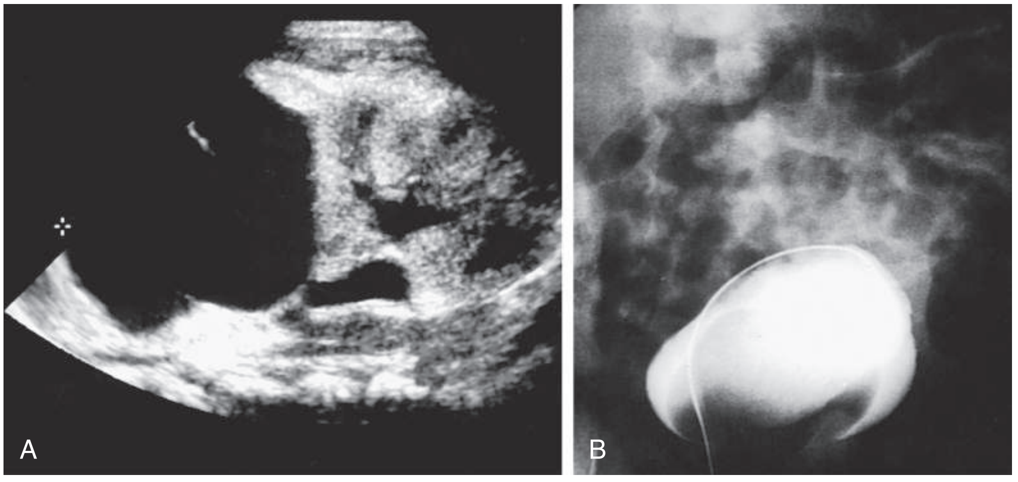

Figure 540-7 **A,** Infant with ectopic ureterocele. Sonogram of the left kidney shows massive dilation of the upper pole and a normal lower pole. **B,** Voiding cystourethrogram shows large ureterocele, draining the left upper pole, in the bladder. No reflux is present.

ureter. When associated with a duplication anomaly, the ureterocele drains the upper renal moiety, which commonly functions poorly or is dysplastic because of congenital obstruction. The lower pole ureter drains into the bladder superior and lateral to the upper pole ureter and may reflux.

An **ectopic ureterocele** extends submucosally into the urethra. Rarely, large ectopic ureteroceles can cause bladder outlet obstruction and retention of urine with bilateral hydronephrosis. In girls, the ureterocele can prolapse from the urethral meatus. Ultrasonography is effective in demonstrating the ureterocele and whether the associated obstructed system is duplicated or single. VCUG usually shows a filling defect in the bladder, sometimes large, corresponding to the ureterocele, and it often shows reflux into the adjacent lower pole collecting system with typical findings of a "drooping lily" appearance to the kidney. Nuclear renal scintigraphy is most accurate in demonstrating whether the affected renal moiety has significant function.

Treatment of ectopic ureteroceles varies among different medical centers and depends on whether the upper pole functions on renal scan and whether there is reflux into the lower pole ureter. If there is nonfunction of the upper pole of the kidney and there is no reflux, treatment usually involves laparoscopic, robotic, or open excision of the obstructed upper pole and most of the associated ureter. If there is function in the upper pole or significant reflux into the lower pole ureter, or if the patient is septic from infection of the hydronephrotic kidney, then transurethral incision with cautery is appropriate initial therapy to decompress the ureterocele. Reflux into the incised ureterocele is common, and subsequent excision of the ureterocele and ureteral reimplantation usually is necessary. An alternative method is to perform a upper-to-lower ureteroureterostomy, allowing the obstructed upper pole ureter to drain through the normal lower ureter; this procedure often is performed with minimally invasive laparoscopic (robotic) technique or through a small incision.

Orthotopic ureteroceles are associated with duplicated or single collecting systems, and the orifice is in the expected location in the bladder (Fig. 540-8). These anomalies usually are discovered during an investigation for prenatal hydronephrosis or a UTI. Ultrasonography is sensitive for detecting the ureterocele in the bladder and hydroureteronephrosis. IVP reveals varying degrees of ureteral and calyceal dilation, and there is a round filling defect in the bladder. In delayed films, cystic dilation of the ureter may be clearly visible and full of contrast material. Transurethral incision of the ureterocele effectively relieves the obstruction, but it can result in vesicoureteral reflux, necessitating ureteral reimplantation later. Some prefer open excision of the ureterocele and reimplantation as the initial form of treatment. Small, simple ureteroceles discovered incidentally without upper tract dilation generally do not require treatment.

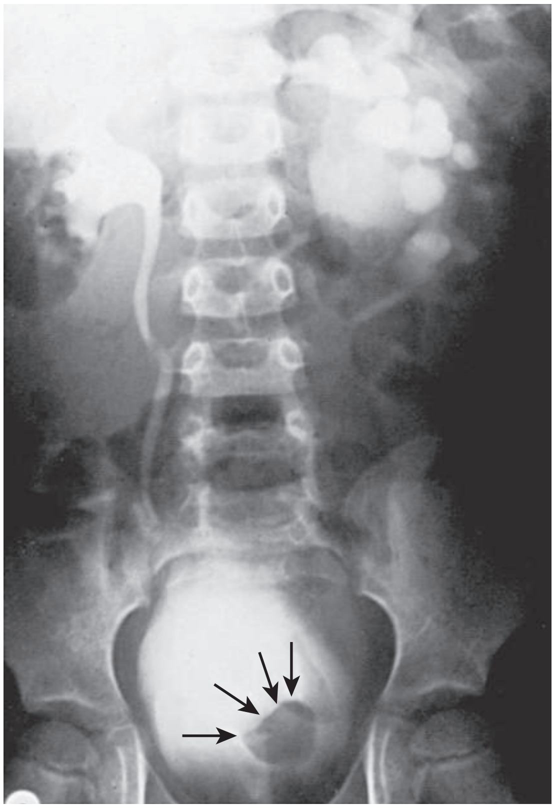

Figure 540-8 Simple intravesical ureterocele. The excretory urogram shows left hydronephrosis and a round filling defect on the left side of the bladder corresponding to a simple ureterocele causing left ureteral obstruction. This lesion was treated by transurethral incision and drainage of the ureterocele.

Megaureter

Table 540-5 presents a classification of megaureters (dilated ureter). Numerous disorders can cause ureteral dilation, and many are nonobstructive.

Megaureters usually are discovered during antenatal sonography, postnatal UTI, hematuria, or abdominal pain. A careful history, physical examination, and VCUG identify causes of secondary megaureters and refluxing megaureters as well as the prune-belly syndrome. Primary obstructed megaureters and nonobstructed megaureters probably represent varying degrees of severity of the same anomaly.

The primary obstructed nonrefluxing megaureter results from abnormal development of the distal ureter, with collagenous tissue replacing the muscle layer. Normal ureteral peristalsis is disrupted, and the proximal ureter widens. In most cases there is not a true stricture. On IVP or an MR urogram, the distal ureter is more dilated in its distal segment and tapers abruptly at or above the junction of the bladder (Fig. 540-9). The lesion may be unilateral or bilateral. Significant hydroureteronephrosis suggests obstruction. Megaureter predisposes to UTI, urinary stones, hematuria, and flank pain because of urinary stasis. In most cases, diuretic renography and sequential sonographic studies can reliably differentiate obstructed from nonobstructed megaureters. In most nonobstructed megaureters, the hydroureteronephrosis diminishes gradually (Fig. 540-10). Truly obstructed megaureters require surgical treatment, with excision of the narrowed segment, ureteral tapering, and reimplantation of the ureter. The results of surgical reconstruction usually are good, but the prognosis depends on preexisting renal function and whether complications develop.

If differential renal function is normal (>45%) and the child is asymptomatic, it is safe to manage the patient with observation with serial ultrasonography and periodic diuretic renography to monitor renal function and drainage. In children with grade 4 hydroureteronephrosis, prophylactic antimicrobial therapy should be prescribed, as these children are prone to upper UTI. If renal function deteriorates, upper urinary tract drainage slows, or UTI occurs, ureteral reimplantation is recommended. Approximately 15% of children with a nonrefluxing megaureter undergo ureteral reimplantation.

Prune-Belly Syndrome

Prune-belly syndrome, also called **triad syndrome** or **Eagle-Barrett syndrome,** occurs in approximately 1 in 40,000 births; 95% of affected children are male. The characteristic association of deficient abdominal muscles, undescended testes, and urinary tract abnormalities probably results from severe urethral obstruction in fetal life (Fig. 540-11). Oligohydramnios and pulmonary hypoplasia are common complications in the perinatal period. Many affected infants are stillborn. Urinary tract abnormalities include massive dilation of the ureters and upper tracts and a very large bladder, with a patent urachus or a urachal diverticulum. Most patients have vesicoureteral reflux. The prostatic urethra usually is dilated, and the prostate is hypoplastic. The anterior urethra may be dilated, resulting in a megalourethra. Rarely, there is urethral stenosis or atresia. The kidneys usually show various degrees of dysplasia, and the testes usually are intraabdominal. Malrotation of the bowel often is present. Cardiac abnormalities occur in 10% of cases; >50% have abnormalities of the musculoskeletal system, including

Table 540-5 Classification of Megaureter

Refluxing		Obstructed		Nonrefluxing and Nonobstructed	
PRIMARY	**SECONDARY**	**PRIMARY**	**SECONDARY**	**PRIMARY**	**SECONDARY**

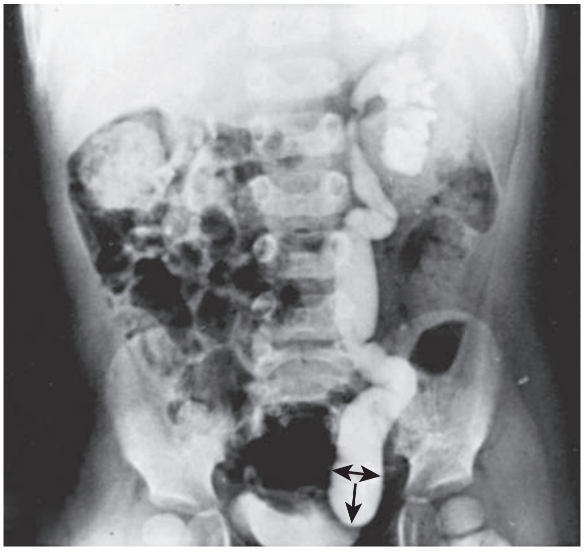

Figure 540-9 Obstructed nonrefluxing megaureter. Excretory urogram in a girl with a history of a febrile urinary tract infection. The right side is normal. The left side reveals hydroureteronephrosis with predominant dilation of the distal ureter. Note the characteristic appearance of the distal ureter. There was no vesicoureteral reflux. The diagnosis of obstruction was confirmed by diuretic renography.

limb abnormalities and scoliosis. In girls, anomalies of the urethra, uterus, and vagina usually are present.

Many neonates with prune-belly syndrome have difficulty with effective bladder emptying because the bladder musculature is poorly developed, and the urethra may be narrowed. When no obstruction is present, the goal of treatment is the prevention of UTI with antibiotic prophylaxis. When obstruction of the ureters or urethra is demonstrated, temporary drainage procedures, such as a vesicostomy, can help to preserve renal function until the child is old enough for surgery. Some children with prune-belly syndrome have been found to have classic or atypical posterior urethral valves. UTIs occur often and should be treated promptly. Correction of the undescended testes by orchidopexy can be difficult in these children because the testes are located high in the abdomen and surgery is best accomplished in the 1st 6 mo of life. Reconstruction of the abdominal wall offers cosmetic and functional benefits.

The prognosis ultimately depends on the degree of pulmonary hypoplasia and renal dysplasia. One third of children with prune-belly syndrome are stillborn or die in the 1st few mo of life because of pulmonary hypoplasia. As many as 30% of the long-term survivors develop end-stage renal disease from dysplasia or complications of infection or reflux and eventually require renal transplantation. Renal transplantation in these children offers good results.

Bladder Neck Obstruction

Bladder neck obstruction usually is secondary to ectopic ureterocele, bladder calculi, or a tumor of the prostate (rhabdomyosarcoma). The manifestations include difficulty voiding, urinary retention, UTI, and bladder distention with overflow incontinence. Apparent bladder neck obstruction is common in cases of posterior urethral valves, but it seldom has any functional significance. Primary bladder neck obstruction is extremely rare.

Posterior Urethral Valves

The most common cause of severe obstructive uropathy in children is posterior urethral valves, affecting 1 in 8,000 boys. The urethral valves are tissue leaflets fanning distally from the prostatic urethra to the external urinary sphincter. A slit-like opening usually separates the leaflets. Valves are of unclear embryologic origin and cause varying degrees of obstruction. Approximately 30% of patients experience end-stage renal disease or chronic renal insufficiency. The prostatic urethra dilates, and the bladder muscle undergoes hypertrophy. Vesicoureteral reflux occurs in 50% of patients, and distal ureteral obstruction can result from a chronically distended bladder or bladder muscle hypertrophy. The renal changes range from mild hydronephrosis to severe renal dysplasia; their severity probably depends on the severity of the obstruction and its time of onset during fetal development. As in other cases of obstruction or renal dysplasia, there may be oligohydramnios and pulmonary hypoplasia.

Affected boys with posterior urethral valves often are discovered prenatally when maternal ultrasonography reveals bilateral hydronephrosis, a distended bladder, and, if the obstruction is severe, oligohydramnios. Prenatal bladder decompression by percutaneous vesicoamniotic shunt or open fetal surgery has been reported. Experimental and clinical evidence of the possible benefits of fetal intervention is lacking, and few affected fetuses are candidates. Prenatally diagnosed posterior urethral valves, particularly when discovered in the 2nd trimester, carry a poorer prognosis than those detected in the 3rd trimester following a normal second fetal ultrasound. In the male neonate, posterior urethral valves are suspected when there is a palpably **distended bladder** and the **urinary stream is weak.** If the obstruction is severe and goes unrecognized during the neonatal period, infants can present later in life with failure to thrive because of uremia or sepsis caused by infection in the obstructed urinary tract. With lesser degrees of obstruction, children present later in life with difficulty in achieving diurnal urinary continence or with UTI. The diagnosis is established with a VCUG (Fig. 540-12) or by perineal ultrasonography.

After the diagnosis is established, renal function and the anatomy of the upper urinary tract should be carefully evaluated. In the healthy neonate, a small polyethylene feeding tube (No. 5 or No. 8 French) is inserted in the bladder and left for several days. Passing the feeding

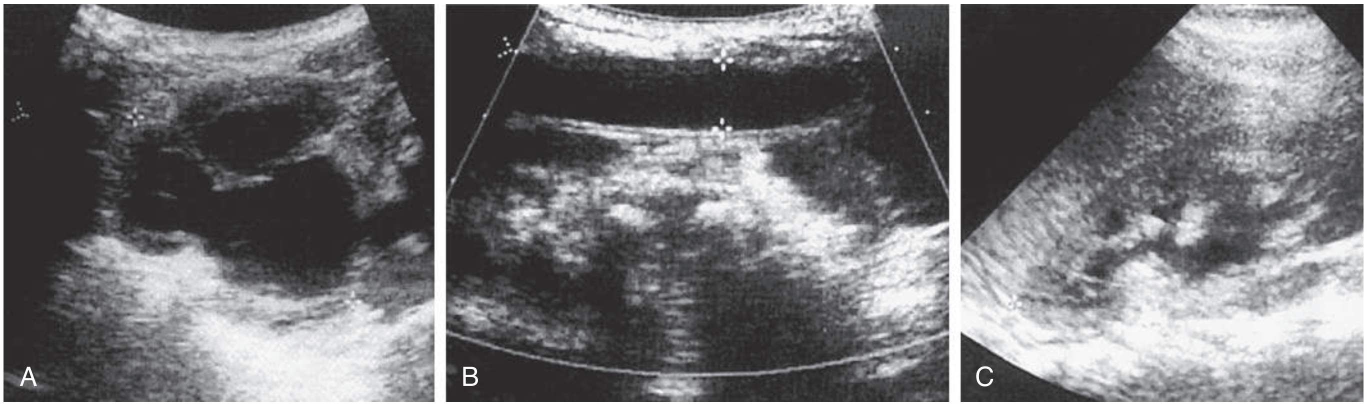

Figure 540-10 Neonate with primary nonrefluxing megaureter. **A,** Renal sonogram shows grade 4 hydronephrosis. **B,** Dilated ureter. Renal scan showed equal function with the contralateral kidney and satisfactory drainage with diuresis stimulation. **C,** Follow-up sonogram at 10 mo shows complete resolution of hydronephrosis.

Figure 540-11 Photograph of a 1,600-g newborn with the prune-belly syndrome. Note the lack of tonicity of the abdominal wall and the wrinkled appearance of the skin.

tube may be difficult, because the tip of the tube can coil in the prostatic urethra. A sign of this problem is that urine drains around the catheter rather than through it. A Foley (balloon) catheter **should not be used**, because the balloon can cause severe bladder spasm, which can produce severe ureteral obstruction.

If the serum creatinine level remains normal or returns to normal, treatment consists of transurethral ablation of the valve leaflets, which is performed endoscopically under general anesthesia. If the urethra is too small for transurethral ablation, temporary vesicostomy is preferred, in which the dome of the bladder is exteriorized on the lower abdominal wall. When the child is older, the valves may be ablated and the vesicostomy closed.

If the serum creatinine level remains high or increases despite bladder drainage by a small catheter, secondary ureteral obstruction, irreversible renal damage, or renal dysplasia should be suspected. In such cases, a vesicostomy should be considered. Cutaneous pyelostomy rarely affords better drainage when compared with cutaneous vesicostomy, and the latter also allows continued bladder growth and gradual improvement in bladder wall compliance.

In the septic and uremic infant, lifesaving measures must include prompt correction of the electrolyte imbalance and control of the infection by appropriate antibiotics. Drainage of the upper tracts by percutaneous nephrostomy and hemodialysis may be necessary. After the patient's condition becomes stable, evaluation and treatment may be undertaken. Posterior valves are diagnosed in some older boys because of a poor stream, diurnal incontinence, or a UTI; these boys generally are treated by primary valve ablation.

Figure 540-12 Voiding cystourethrogram in an infant with posterior urethral valves. Note the dilation of the prostatic urethra and the transverse linear filling defect corresponding to the valves.

Favorable prognostic factors include a normal prenatal ultrasonogram between 18 and 24 wk of gestation, a serum creatinine level <0.8-1.0 mg/dL after bladder decompression, and visualization of the corticomedullary junction on renal sonography. In several situations, a "popoff valve" can occur during urinary tract development, which preserves the integrity of 1 or both kidneys. For example, 15% of boys with posterior urethral valves have unilateral reflux into a nonfunctioning dysplastic kidney, termed the **VURD syndrome** (*v*alves, *u*nilateral *r*eflux, *d*ysplasia). In these boys, the high bladder pressure is dissipated into the nonfunctioning kidney, allowing normal development of the contralateral kidney. In newborn boys with urinary ascites, the urine generally leaks out from the obstructed collecting system through the renal fornices, allowing normal development of the kidneys. Unfavorable prognostic factors include the presence of oligohydramnios in utero, identification of hydronephrosis before 24 wk of gestation, a serum creatinine level >1.0 mg/dL after bladder decompression, identification of cortical cysts in both kidneys, and persistence of diurnal incontinence beyond 5 yr of age.

The prognosis in the newborn is related to the child's degree of pulmonary hypoplasia and potential for recovery of renal function. Severely affected infants often are stillborn. Of those who survive the neonatal period, approximately 30% eventually require kidney transplantation and 15% have renal insufficiency. In some series, kidney transplantation in children with posterior urethral valves has a lower success rate than does transplantation in children with normal bladders, presumably because of the adverse influence of altered bladder function on graft function and survival.

After valve ablation, antimicrobial prophylaxis is beneficial in preventing UTI, because hydronephrosis to some degree often persists for many years. These boys should be evaluated annually with a renal ultrasonogram, physical examination including assessment of somatic growth and blood pressure, urinalysis, and determination of serum levels of electrolytes. Many boys have significant polyuria resulting from a concentrating defect secondary to prolonged obstructive uropathy. If these children acquire a systemic illness with vomiting and/or diarrhea, urine output cannot be used to assess their hydration status. They can become dehydrated quickly, and there should be a low threshold for hospital admission for intravenous rehydration. Some of these patients have renal tubular acidosis, requiring oral bicarbonate therapy. If there is any significant degree of renal dysfunction, growth impairment, or hypertension, the child should be followed closely by a pediatric nephrologist. When vesicoureteral reflux is present, expectant treatment and prophylactic doses of antibacterial drugs are advisable. If breakthrough UTI occurs, surgical correction should be undertaken.

After treatment, boys with urethral valves often do not achieve diurnal urinary continence as early as other boys. Incontinence can result from a combination of factors, including uninhibited bladder contractions, poor bladder compliance, bladder atonia, bladder neck dyssynergia, or polyuria. Often these boys require urodynamic evaluation with urodynamics or videourodynamics to plan therapy. Boys with noncompliance are at significant risk for ongoing renal damage, even in the absence of infection. Overnight catheter drainage has been shown to be beneficial in boys with polyuria and can help preserve renal function. Urinary incontinence usually improves with age, particularly after puberty. Meticulous attention to bladder compliance, emptying, and infection can improve results in the future.

Urethral Atresia

The most severe form of obstructive uropathy in boys is urethral atresia, a rare condition. In utero there is a distended bladder, bilateral hydroureteronephrosis, and oligohydramnios. In most cases, these infants are stillborn or succumb to pulmonary hypoplasia. Some boys with prune-belly syndrome also have urethral atresia. If the urachus is patent, oligohydramnios is unlikely and the infant usually survives. Urethral reconstruction is difficult, and most patients are managed with continent urinary diversion.

Urethral Hypoplasia

Urethral hypoplasia is a rare form of obstructive uropathy in boys that is less severe than urethral atresia. In urethral hypoplasia, the urethral lumen is extremely small. Neonates with urethral hypoplasia typically have bilateral hydronephrosis and a distended bladder. Passage of a small pediatric feeding tube through the urethra is difficult or impossible. Usually a cutaneous vesicostomy must be performed to relieve upper urinary tract obstruction, and the severity of renal insufficiency is variable. The most severely affected boys have end-stage renal disease. Treatment includes urethral reconstruction, gradual urethral dilation, or continent urinary diversion.

Urethral Strictures

Urethral strictures in boys usually result from urethral trauma, either iatrogenic (catheterization, endoscopic procedures, previous urethral reconstruction) or accidental (straddle injuries, pelvic fractures). Because these lesions can develop gradually, the decrease in force of the urinary stream is seldom noticed by the child or the parents. More commonly, the obstruction causes symptoms of bladder instability, hematuria, or dysuria. Catheterization of the bladder usually is impossible. The diagnosis is made by a retrograde urethrogram, in which contrast is injected toward the bladder through a catheter inserted into the distal urethra. Ultrasonography also has been used to diagnose urethral strictures. Endoscopy is confirmatory. Endoscopic treatment of short strictures by direct vision urethrotomy is often successful initially and results in a profoundly improved urinary stream, but often the stricture recurs and is found at long-term follow-up. Longer strictures surrounded by periurethral fibrosis often require urethroplasty. Repeated endoscopic procedures generally should be avoided, because they can cause additional urethral damage. Noninvasive measurement of the urinary flow rate and pattern is useful for diagnosis and follow-up.

In girls, true urethral strictures are rare because the female urethra is protected from trauma, particularly in childhood. In the past it was thought that a distal urethral ring commonly caused obstruction of the female urethra and UTI and that affected girls benefited from urethral dilation. The diagnosis was suspected when a "spinning top" deformity of the urethra was found in the VCUG (see Fig. 543-3 in Chapter 543) and was confirmed by urethral calibration. There is no correlation between the radiologic appearance of the urethra in the VCUG and the urethral caliber and no significant difference in urethral caliber between girls with recurrent cystitis and normal age-matched controls. The finding usually is secondary to detrusor–sphincter dyssynergia. Consequently, urethral dilation in girls rarely is indicated.

Anterior Urethral Valves and Urethral Diverticula in the Male

Anterior urethral valves are rare. The obstruction is not obstructing valve leaflets, as occurs in the posterior urethra. Rather, it is a urethral diverticulum in the penile urethra that expands during voiding. Distal extension of the diverticulum causes extrinsic compression of the distal penile urethra, causing urethral obstruction. Typically there is a soft mass on the ventral surface of the penis at the penoscrotal junction. In addition, the urinary stream often is weak, and the physical findings associated with posterior urethral valves often are present. The diverticulum may be small and minimally obstructive, or, in other cases, may be severely obstructive and cause renal insufficiency. The diagnosis is suspected on physical examination and is confirmed by the VCUG. Treatment involves open excision of the diverticulum or transurethral excision of the distal urethral cusp. Urethral diverticula occasionally occur after extensive hypospadias repair.

Fusiform dilation of the urethra or **megalourethra** can result from underdevelopment of the corpus spongiosum and support structures of the urethra. This condition is commonly associated with the prune-belly syndrome.

Male Urethral Meatal Stenosis

See Chapter 544 for information on urethral meatal stenosis in males.

Chapter 541

Anomalies of the Bladder

Jack S. Elder

BLADDER EXSTROPHY

Exstrophy of the urinary bladder occurs in approximately 1 in 35,000-40,000 births. The male : female ratio is 2 : 1. The severity ranges from simple **epispadias** (in boys) to complete exstrophy of the cloaca involving exposure of the entire hindgut and the bladder (termed **cloacal exstrophy**).

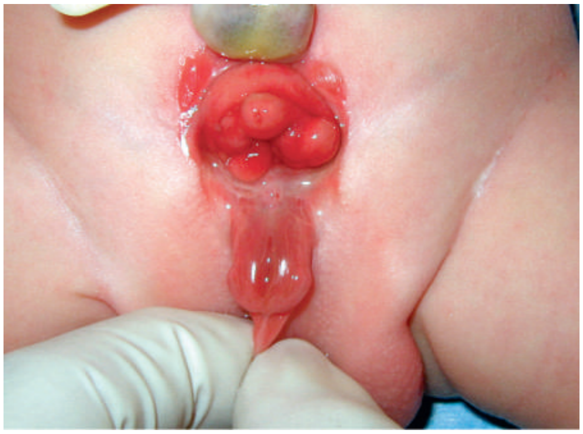

Figure 541-1 Classic bladder exstrophy in a newborn boy. The bladder is exposed in the midline, the umbilical cord is displaced caudad, the penis is epispadiac, and the scrotum is broad.

Clinical Manifestations

Anomalies of the bladder are hypothesized to result when the mesoderm fails to invade the cephalad extension of the cloacal membrane; the extent of this failure determines the degree of the anomaly. In classic bladder exstrophy (Fig. 541-1), the bladder protrudes from the abdominal wall and its mucosa is exposed. The umbilicus is displaced downward, the pubic rami are widely separated in the midline, and the rectus muscles are separated. In boys, there is complete epispadias with dorsal chordee, and the overall penile length is approximately half that of unaffected boys. The scrotum typically is separated slightly from the penis and is wide and shallow. Undescended testes and inguinal hernias are common. Girls also have epispadias, with separation of the 2 halves of the clitoris and wide separation of the labia. The anus is displaced anteriorly in both sexes, and there may be rectal prolapse. The pubic rami are widely separated. Persons with exstrophy tend to be shorter than normal.

The consequences of untreated bladder exstrophy are total urinary incontinence and an increased incidence of bladder cancer, usually adenocarcinoma. The genital deformities can produce sexual disability in both sexes, particularly in males. The wide separation of the pubic rami causes a characteristic broad-based gait but no significant disability. In classic bladder exstrophy, the upper urinary tracts usually are normal.

Treatment

Management of bladder exstrophy should start at birth. The bladder should be covered with plastic wrap to keep the bladder mucosa moist. **Application of gauze or petroleum-gauze to the bladder mucosa should be avoided, because significant inflammation will result.** The infant should be transferred promptly to a center with pediatric urologic and anesthetic support for the treatment of such anomalies. These children are prone to **latex allergy,** so latex precautions should be practiced in their care.

There are 2 surgical approaches: staged reconstruction and total single-stage reconstruction. Most babies also undergo bilateral iliac osteotomy, which allows the pubic symphysis to be approximated, which supports the bladder closure. In a staged reconstruction, the initial stage is bladder closure, the 2nd stage (in boys) is epispadias repair, and the final stage is bladder neck reconstruction. The single-stage reconstruction attempts to reconstruct the entire malformation in a single procedure. When this operation is performed in the newborn, there is an increased risk of intraoperative penile injury and postoperative hydronephrosis, compared with the staged reconstruction. The complication rate is high with both approaches and there is no consensus on which is better.

Although bladder closure within 48 hr has been the standard in the past, more recently, many centers of excellence defer the procedure for 1-2 wk to be certain that the appropriate experienced surgical and anesthetic team is available. During bladder exstrophy closure, the abdominal wall is mobilized and the pubic rami are brought together in the midline following pelvic osteotomy. Early bladder closure can be performed in almost all neonates with classic bladder exstrophy. Treatment should be deferred in selected situations when surgical therapy would be excessively risky or complex, such as in a premature baby or when it would have to be performed by inexperienced surgeons. In the staged approach, in boys, epispadias repair usually is performed at 1-2 yr of age. At this point the child has total urinary incontinence because there is no functional external urinary sphincter. At 3-6 yr, if the bladder is sufficiently large, bladder neck reconstruction is performed to try to create a functional sphincter.

Total single-stage reconstruction includes closure of the bladder, closure of the abdominal wall, and, in boys, correction of epispadias using a technique of penile disassembly, in which the 2 corpora cavernosa and the midline urethra are mobilized separately into 3 parts. Postoperatively, the infant's upper urinary tract is monitored closely for the possible development of hydronephrosis and infection. Most infants with bladder exstrophy have vesicoureteral reflux and should receive antibiotic prophylaxis. The final stage of reconstruction involves creation of a sphincter muscle for bladder control and correction of the vesicoureteral reflux. At this point the child is 3-6 yr old, the bladder capacity should be at least 80-90 mL, and the child must have gained rectal control. Typically, bladder capacity is monitored every 12-24 mo using cystoscopy under anesthesia.

At puberty, often the pubic hair is distributed to the sides of the external genitals. A monsplasty can performed to provide a normal escutcheon.

Long-Term Prognosis

This plan of treatment has yielded a continence rate of 60-70% in a few centers, with <15% deterioration of the upper urinary tract. This continence rate reflects not only the successful reconstruction but also the quality and size of the bladder. The reconstructed bladder neck does not relax during voiding as in a normal child; instead the patient must void by Valsalva. Children who undergo reconstructive surgery as newborns have a greater chance of obtaining a normally functioning bladder.

Children who remain incontinent for more than 1 yr after bladder neck reconstruction or those who are not eligible for bladder neck reconstruction because of a small bladder capacity are candidates for an alternative reconstructive procedure to achieve dryness. In selected cases, cystoscopic injection of dextranomer or polydimethylsiloxane microspheres into the bladder neck can provide sufficient bladder neck coaptation to establish continence. Alternatively, if the child is not a candidate for endoscopic therapy, options include:

- Augmentation cystoplasty, in which the bladder is enlarged with a patch of small or large bowel to increase its capacity.
- Creation of a neobladder out of small and large bowel with placement of a continent abdominal stoma through which clean intermittent catheterization can be performed.
- Placement of an artificial urinary sphincter, with possible augmentation cystoplasty.
- Ureterosigmoidostomy, in which the ureters are detached from the bladder and sutured to the sigmoid colon; individuals void urine and stool from the rectum and rely on their anal sphincter for continence.
- Mainz II procedure, in which the sigmoid colon is reconfigured into a "bladder" into which the ureters are connected, and the patient voids 3-6 times daily through the rectum, and the stool tends to be more solid.

Ureterosigmoidostomy carries a significant risk of chronic pyelonephritis (see Chapter 538), upper urinary tract damage, metabolic acidosis resulting from absorption of hydrogen ion and chloride in the intestine, and at least a 15% long-term risk of colon carcinoma. Patients from less-developed countries often undergo the Mainz II procedure because the continence rate is high and pyelonephritis and upper tract changes are uncommon.

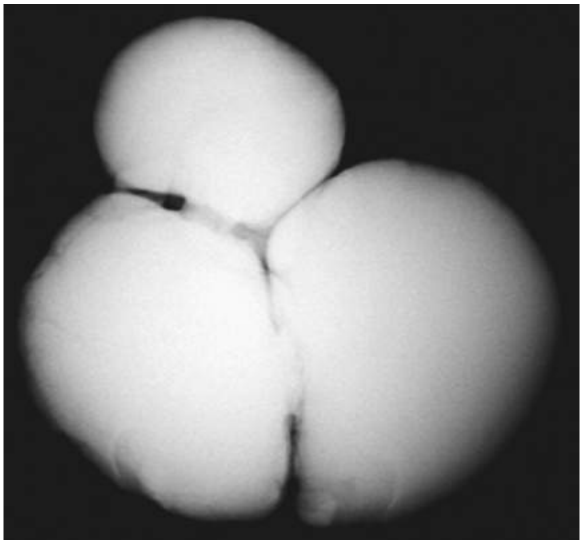

Figure 541-3 Girl with Menkes syndrome with multiple large bladder diverticula causing inability to void and recurrent urinary tract infections. The condition was managed by bladder diverticulectomy.

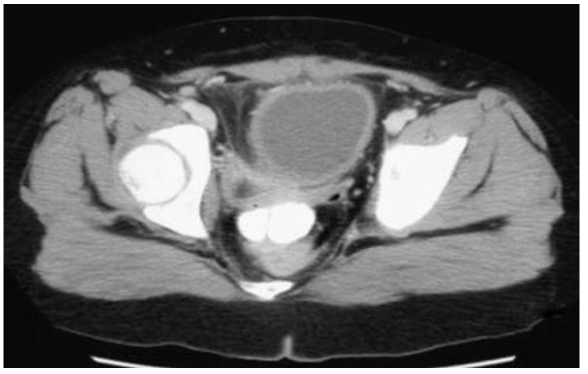

Figure 541-4 CT scan demonstrating infected urachal abscess in an 8 yr old girl. The condition was managed by drainage and excision.

Late follow-up has shown that although men with exstrophy have a penis that is half normal length, they usually experience satisfactory sexual function. Fertility has been low, possibly because of iatrogenic injury to the secondary sexual organs during reconstruction. With artificial reproductive technology, nearly all men can be fertile. In women, fertility is not affected, but uterine prolapse during pregnancy is a problem. In women who have undergone a continent urinary diversion, delivery by cesarean section may be necessary.

OTHER EXSTROPHY ANOMALIES

Children with more complex cases of **cloacal exstrophy,** which has an incidence of 1 in 400,000, have an omphalocele and severe abnormalities of the colon and the rectum and often have short bowel syndrome (see Chapter 338.7), the most devastating anomaly managed by pediatric urologists. Approximately 50% of patients have an upper urinary tract anomaly, and 50% have spina bifida (see Chapter 591). Children with cloacal exstrophy do not achieve normal urine or stool continence. Reconstructive techniques result in a satisfactory outcome in most patients with permanent urinary diversion (either ileal conduit or continent urinary diversion) and a colostomy. Because the penis in boys with cloacal exstrophy usually is diminutive, genital reconstruction in boys with cloacal exstrophy has been unsatisfactory. Until recently, most specialists recommended assigning a female gender to such infants, but currently there is debate whether these children, who have a 46,XY karyotype and androgen imprinting in utero, can have a satisfactory female gender identity (see Chapter 110.2). Many assume male gender characteristics by adolescence. Decisions regarding gender assignment should be made jointly by the physicians caring for the infant (surgical team, pediatric endocrinologist, child psychiatrist, and ethicist) and family.

Epispadias is in the spectrum of exstrophy anomalies, affecting approximately 1 in 117,000 boys and 1 in 480,000 girls. In boys, the diagnosis is obvious because the prepuce is distributed primarily on the ventral aspect of the penile shaft and the urethral meatus is on the dorsum of the penis. Distal epispadias in boys usually is associated with normal urinary control and normal upper urinary tracts and should be repaired by 6-12 mo of age. In girls, the clitoris is bifid and the urethra is split dorsally (Fig. 541-2). In more severely affected boys and in all girls with epispadias, there is total urinary incontinence because the sphincter is incompletely formed, and there is wide separation of the pubic rami. These children require surgical reconstruction of the bladder neck, similar to the final management stage in children with classic bladder exstrophy.

BLADDER DIVERTICULA

Bladder diverticula develop as herniations of bladder mucosa between defects of bladder smooth muscle fibers. Primary bladder diverticula usually develop at the ureterovesical junction and may be associated with vesicoureteral reflux, because the diverticulum interferes with the normal flap-valve attachment between the ureter and bladder. In rare circumstances the diverticulum is so large that it interferes with normal micturition by obstructing the bladder neck. Bladder diverticula also commonly are associated with distal urethral obstruction such as posterior urethral valves or neurogenic bladder dysfunction. They occur commonly in children with connective tissue disorders including Williams syndrome, Ehlers-Danlos syndrome, and Menkes syndrome (Fig. 541-3). Small diverticula require no treatment other than that of the primary disease, whereas large diverticula can contribute to inefficient voiding, residual urine, urinary stasis, and urinary tract infections and should be excised.

URACHAL ANOMALIES

The urachus is an embryologic canal connecting the dome of the fetal bladder with the allantois, a structure that contributes to the formation of the umbilical cord. The lumen of the urachus is normally obliterated during embryonic development, transforming the urachus into a solid cord. Urachal abnormalities are more common in boys than in girls. A **patent urachus** can occur as an isolated anomaly; it may be associated with prune-belly syndrome or posterior urethral valves (see Chapter 540). In this condition there is continuous urinary drainage from the umbilicus. The tract should be excised. Another urachal anomaly is the **urachal cyst**, which can become infected. Typical symptoms and physical findings include suprapubic pain, fever, irritative voiding symptoms, and an infraumbilical mass, which can be erythematous. Diagnosis is made by ultrasonography or CT (Fig. 541-4).

Treatment is intravenous antibiotic therapy and drainage and excision. Other urachal anomalies include the **vesicourachal diverticulum**, which is a diverticulum of the bladder dome, and **umbilical–urachal sinus**, which is a blind external sinus that opens at the umbilicus. These lesions should be excised.

Chapter 542

Neuropathic Bladder

Jack S. Elder

Neuropathic bladder dysfunction in children usually is congenital, generally resulting from neural tube defects or other spinal abnormalities. Acquired diseases and traumatic lesions of the spinal cord are less common. Central nervous system tumors, sacrococcygeal teratoma, spinal abnormalities associated with imperforate anus (see Chapter 344), and spinal cord trauma also can result in abnormal innervation of the bladder and/or sphincter.

NEURAL TUBE DEFECTS

Neural tube defects, resulting from failure of the neural tube to close spontaneously between the 3rd and 4th wk in utero, result in abnormalities of the vertebral column that affect spinal cord function, including myelomeningocele and meningocele (see Chapter 591). A few medical centers in the United States have been performing antenatal myelomeningocele closure. Long-term results from one large trial (the “MOMS trial”), have not shown a definite improvement in lower urinary tract function, although some children have demonstrated nearly normal bladder function, and overall there has been a significant reduction in the need for ventriculoperitoneal shunting.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The most important urologic consequences of neuropathic bladder dysfunction associated with neural tube defects are urinary incontinence (see Chapter 543), urinary tract infections (UTIs; see Chapter 538), and hydronephrosis from vesicoureteral reflux (see Chapter 539), or detrusor–sphincter dyssynergia (see Chapter 540). Pyelonephritis and renal functional deterioration (see Chapter 535) are common causes of premature death of affected patients.

In the neonate, renal ultrasonography, assessment of postvoid residual urine volumes, and a voiding cystourethrogram are performed after closure of the myelomeningocele. Approximately 10-15% of newborns with myelomeningocele have hydronephrosis, and renal malformations are common; 25% have vesicoureteral reflux. A urodynamic study also should be performed. This study involves filling the bladder with saline, measuring the bladder volume and pressure, and assessing sphincter tone. During bladder filling, the bladder might show (1) uninhibited (premature) contractions (termed hyperreflexia) at low volumes, (2) normal bladder volume with contraction at an appropriate volume, or (3) atonia (lack of bladder contraction). Bladder compliance or elasticity also may be reduced. The sphincter can show (1) normal tonicity with relaxation during bladder contraction, (2) reduced or absent tonicity, or (3) normal or increased tonicity that increases during a bladder contraction (termed detrusor-sphincter dyssynergia) (Fig. 542-1).

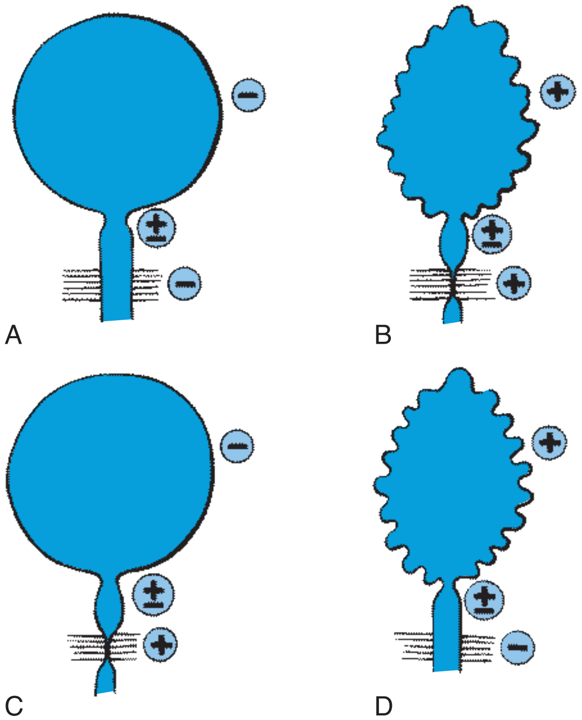

Figure 542-1 **Grouping of neurogenic bladder dysfunction according to the innervation, tonicity, and coordination of the detrusor and sphincters described by Guzman.** This grouping is based on data from imaging studies, cystometrography, and electromyography of the sphincters. Patients in group B are at risk of developing reflux and hydronephrosis. For guidance in the treatment of incontinence, group A benefits from procedures that increase outlet resistance, group B from anticholinergics or bladder augmentation surgery, and group C from intermittent catheterization. Group D requires both increased outlet resistance and pharmacologic or surgical bladder enlargement. Most patients require intermittent catheterization to empty. *(Modified from Gonzalez R: Urinary incontinence. In Kelalis PK, King LR, Belman AB, editors:* Clinical pediatric urology, *Philadelphia, 1992, WB Saunders, p. 387.)*

RENAL DAMAGE

Renal damage usually results from detrusor–sphincter dyssynergia. This dyssynergia causes functional obstruction of the bladder outlet, leading to bladder muscle hypertrophy and trabeculation, high intravesical pressure, and transmission of this high pressure into the upper urinary tracts, causing hydronephrosis (Fig. 542-2). Vesicoureteral reflux and UTI compound the problem. Treatment includes reduction of bladder pressure with anticholinergic drugs (e.g., oxybutynin, 0.2 mg/kg/24 hr in 2 or 3 divided doses) and clean intermittent catheterization every 3-4 hr. If the child has vesicoureteral reflux or UTI, antimicrobial prophylaxis also is prescribed.

Temporary urinary diversion by cutaneous vesicostomy is an alternative in the newborn or infant with severe reflux, if intermittent catheterization is difficult or anticholinergic medications are not well tolerated. Another option to treat the severely trabeculated bladder is transurethral injection of botulinum toxin (Botox) into the detrusor muscle, which reduces bladder hypertonicity for approximately 6 mo. A different approach in these children is to temporarily inactivate the tight sphincter by urethral overdilation or transurethral injection of botulinum toxin into the sphincter. In children with upper tract changes, continuous overnight bladder drainage allows significant bladder relaxation and can reduce bladder wall thickening and lessen hydronephrosis.

Clean intermittent catheterization and anticholinergic therapy cure reflux in up to 80% of children with grade I or II reflux. Children with more severe reflux often require subureteral endoscopic injection therapy (see Chapter 539) or open antireflux surgery followed by intermittent catheterization and anticholinergic drugs. In older children with myelomeningocele with high-grade reflux, UTI, and hydronephrosis, augmentation enterocystoplasty (enlarging the bladder with a

Figure 542-2 Voiding cystourethrogram in an infant with myelodysplasia shows a severely trabeculated bladder with multiple diverticula and grade V (out of V) right vesicoureteral reflux. Evaluation showed severe detrusor–sphincter dyssynergia.

patch of intestine) with intermittent catheterization may be necessary. This intervention allows a normal capacity bladder with low bladder pressure and effective drainage of the bladder.

URINARY INCONTINENCE

Incontinence in the child with neuropathic bladder can result from total or partial denervation of the sphincter, bladder hyperreflexia, poor bladder compliance, chronic urinary retention, or a combination of these factors.

Incontinence often is addressed around 4 yr of age and is tailored to the individual child. Nearly all children require clean intermittent catheterization to stay dry. This technique allows efficient bladder emptying with minimal risk of symptomatic UTI. The urinary tract should be reevaluated with renal ultrasonography, a voiding cystourethrogram, and a urodynamic study, including bladder capacity. If the external sphincter tone is sufficient and the bladder has adequate compliance, intermittent catheterization every 3-4 hr usually is successful in keeping the child dry. If there are unstable bladder contractions, an anticholinergic medication such as oxybutynin chloride, hyoscyamine, or tolterodine is prescribed to increase bladder capacity. If there is sphincter incompetence, α-adrenergic medications are prescribed to enhance outlet resistance. Bacteriuria is seen in up to 50% of children using intermittent self-catheterization, but it seldom causes symptoms. In the absence of reflux, there seems to be little cause for concern. Performing intermittent catheterization with a new catheter (hydrophilic or standard silicone) each time also is quite effective in preventing bacteriuria and avoids the need for antibiotic prophylaxis. With this treatment plan, 40-85% of patients are dry, depending on the definition of continence; some children wear a pad in their underwear or a diaper but feel that they are dry.

If there is persistent incontinence despite medical therapy, reconstructive urinary tract surgery nearly always can provide complete or satisfactory continence. If urethral resistance is low, bladder neck reconstructive procedures such as a periurethral sling often are successful. Alternatively, implantation of an artificial sphincter usually is successful. This sphincter consists of an inflatable cuff that is placed around the bladder neck, a pressure-regulating balloon implanted in the extraperitoneal space, and a pumping mechanism that is implanted in the scrotum of boys and in the labia majora of girls. If the bladder capacity or bladder compliance is low, or if there are persistent uninhibited contractions despite anticholinergic therapy, enlargement of the bladder with a patch of small or large intestine, termed **augmentation cystoplasty** or **enterocystoplasty,** is effective.

These patients still need to perform clean intermittent catheterization. If urethral catheterization is difficult, a continent urinary stoma may be incorporated into the urinary tract reconstruction. A common method is the **Mitrofanoff procedure,** in which the appendix is isolated from the cecum on its vascular pedicle and is interposed between the bladder and abdominal wall to allow intermittent catheterization through a dry stoma. An ileal conduit with a bag on the abdominal wall is rarely used.

Complications of Augmentation Cystoplasty

Urinary Tract Infection

The urine may be colonized with Gram-negative bacteria, and attempts to sterilize the urine for prolonged periods usually fail. There is no evidence that chronic bacteriuria in patients who have had enterocystoplasty is associated with renal damage; therefore, only symptomatic UTIs should be treated.

Metabolic Acidosis

The enteric mucosal surface in contact with the urine absorbs ammonium, chloride, and hydrogen ions and loses potassium. Hyperchloremic metabolic acidosis can result, possibly requiring medical treatment (see Chapter 55). Chronic acidosis can compromise skeletal growth. This condition is common with colocystoplasty but is rare with ileocystoplasty. Metabolic acidosis also is common in patients with compromised renal function. To overcome this limitation of enterocystoplasty in patients with chronic renal insufficiency, a composite augmentation using stomach and small or large bowel gastric segment can be used. The stomach secretes chloride and hydrogen ions; thus, preexisting metabolic acidosis remains stable or improves.

Spontaneous Perforation

Perforation of the augmented bladder is a life-threatening complication that results most often from acute or chronic overdistention of the augmented bladder. Patients with this complication typically present with severe abdominal pain and signs of peritonitis. Prompt diagnosis and treatment with exploratory laparotomy and bladder closure are necessary. Meticulous adherence to the prescribed program of intermittent catheterization to avoid bladder overdistention is important.

Bladder Calculi

Bladder calculi have developed in as many as 70% of children followed for 10 yr after enterocystoplasty. The calculi develop in response to mucus that accumulates in the bladder and act as a nidus for stone formation. This complication can be prevented by daily irrigation of the bladder with sterile saline.

Malignant Neoplasm

Invasive transitional cell carcinoma has been reported in nearly 2% of patients undergoing enterocystoplasty (compared with a 1% risk in spina bifida patients without enterocystoplasty). The pathogenesis is uncertain but is speculated that it is related to bacteriuria and the bowel-bladder contact. The risk seems to be highest following gastrocystoplasty. The risk seems to increase 10 yr following enterocystoplasty. Although these patients probably should undergo screening, there are no guidelines or recommendations regarding this practice. It seems appropriate to advise yearly endoscopic examinations or urine cytologic studies beginning in the 10th postoperative year.

Future Management

The development of a tissue-engineered bladder using a composite scaffold, which could be attached to the dome of the bladder to increase capacity and compliance, might help patients achieve continence

(Fig. 542-3). In addition, there is a nerve-rerouting procedure in which the dorsal nerve root from the lumbar nerve is sutured to the ventral sacral nerve root, allowing the child to scratch the thigh to stimulate a bladder contraction. This procedure is controversial.

ASSOCIATED DISORDERS

Constipation

Many patients with spina bifida also have bowel problems with constipation, and a vigorous bowel regimen is important. Some benefit from the **Malone antegrade continence enema procedure,** in which the appendix is brought out to the skin to allow a catheter to be inserted into the cecum for antegrade enema. The stoma is continent, and an antegrade enema can be performed with tap water each day. This form of management allows the patient to be continent of stool and be more self-sufficient.

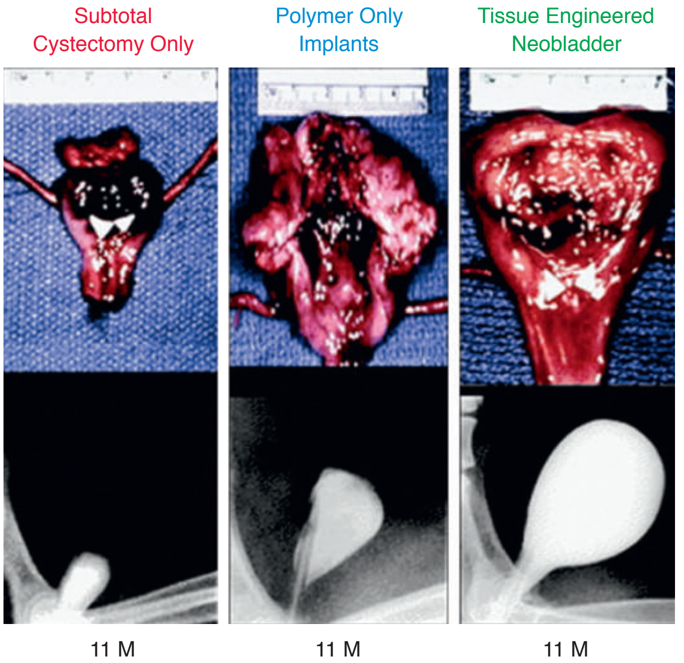

Figure 542-3 Gross specimens and cystograms at 11 mo of the cystectomy-only, nonseeded controls, and cell-seeded tissue engineered bladder replacements in dogs. The cystectomy-only bladder had a capacity of 22% of the preoperative value and a decrease in bladder compliance to 10% of the preoperative value. The nonseeded controls showed significant scarring and had a capacity of 46% of the preoperative value and a decrease in bladder compliance to 42% of the preoperative value. An average bladder capacity of 95% of the original precystectomy volume was achieved in the cell-seeded tissue engineered bladder replacements, and the compliance showed almost no difference from preoperative values that were measured when the native bladder was present (106%). *(From Atala A: Bioengineered tissues for urogenital repair in children,* Pediatr Res *63:569–575, 2008.)*

Latex Allergy

Latex allergy is a very serious problem encountered by as many as half of patients with spina bifida and other urologic conditions who require clean intermittent catheterization and urinary tract reconstructive procedures. This immunoglobulin E–mediated allergy is acquired and is secondary to repeated exposure to the latex allergen. Latex allergy can manifest as watery eyes, sneezing, itching, hives, or anaphylaxis when blowing up a balloon or if an examiner is using latex gloves. Intraoperatively, a sensitized patient can experience anaphylactic shock. A latex-free environment should be provided for all children with spina bifida in the office, during hospitalization, and during operative procedures. Affected children also should wear a medical alert bracelet.

Occult Spinal Dysraphism

Approximately 1 in 4,000 patients have occult spinal dysraphism, a category that includes lipomeningocele, intradural lipoma, diastematomyelia, tight filum terminale, dermoid cyst-sinus, aberrant nerve roots, anterior sacral meningocele, and cauda equina tumor. More than 90% of patients have a cutaneous abnormality overlying the lower spine, including a small dimple, tuft of hair, dermal vascular malformation, or subcutaneous lipoma (Fig. 542-4). Often these children have high-arched feet, discrepancy in muscle size and strength between the legs, and a gait abnormality. Newborns and young infants often have a normal neurologic examination. Older children often have absent perineal sensation and back pain. Lower urinary tract function is abnormal in 40% of patients, including incontinence, recurrent UTI, and fecal soiling. The likelihood of a normal examination is inversely related to the child's age at surgical correction of the spinal lesion. In infants with abnormal urodynamics, 60% revert to normal; in older children, only 27% become normal. Management of the urinary tract in other children is similar to that described earlier for neural tube defects.

Sacral Agenesis

Sacral agenesis is defined as the absence of part or all of ≥2 lower vertebral bodies. This condition is more common in the offspring of women with diabetes. These children have a flattened buttock and a low, short gluteal cleft but usually have no orthopedic deformity, although some have high-arched feet. Palpation of the coccygeal area detects the absent vertebrae. Approximately 20% of cases are undetected until the age of 3-4 yr; many are diagnosed after unsuccessful

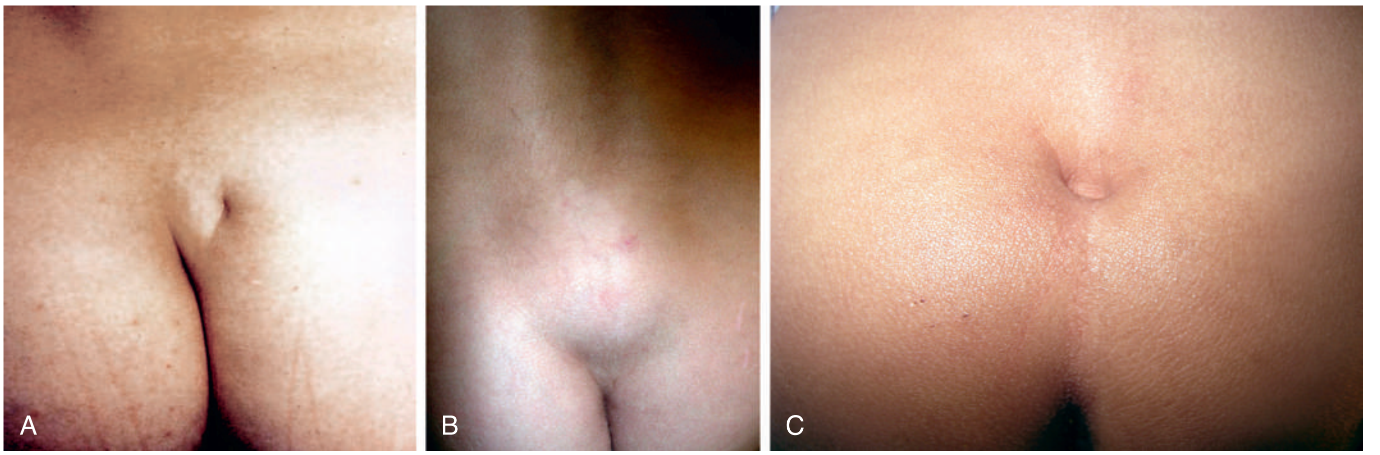

Figure 542-4 A, Buttocks of teenage boy with tethered cord secondary to lipomeningocele. Note sacral dimple and deviation of gluteal fold to the left. **B,** Fat deposit over sacrum in girl with tethered cord secondary to lipomeningocele. **C,** Deep sacral pit in child with neuropathic bladder.

toilet training. Urodynamic studies in these children show a variety of patterns, and most need clean intermittent catheterization and pharmacotherapy to stay dry.

Imperforate Anus

Approximately 30-45% of children with a high imperforate anus have a neuropathic bladder, often because of sacral agenesis. Newborns with imperforate anus should undergo a spinal ultrasound during their initial evaluation, and if these children have difficulty with toilet training, complete urologic evaluation with upper and lower urinary tract imaging and urodynamics should be performed. See Chapter 344 for further details.

Cerebral Palsy

Children with cerebral palsy (see Chapter 598.1) often have reasonable bladder control. However, they achieve continence at a later age than unaffected children. Overall, 25-50% are incontinent, and the risk is directly related to the severity of physical impairment. Their upper urinary tracts usually are normal. Urodynamic studies have shown that most have uninhibited bladder contractions. Timed voiding and anticholinergic therapy are usually effective. Clean intermittent catheterization rarely is necessary.

Enuresis and Voiding Dysfunction

Jack S. Elder

NORMAL VOIDING AND TOILET TRAINING

Fetal voiding occurs by reflex bladder contraction in concert with simultaneous contraction of the bladder and relaxation of the sphincter. Urine storage results from sympathetic and pudendal nerve-mediated inhibition of detrusor contractile activity accompanied by closure of the bladder neck and proximal urethra with increased activity of the external sphincter. The infant has coordinated reflex voiding as often as 15-20 times/day. Over time, bladder capacity increases. In children up to the age of 14 yr, the mean bladder capacity in ounces is equal to the age (in years) plus 2.

At 2-4 yr, the child is developmentally ready to begin toilet training. To achieve conscious bladder control, several conditions must be present: awareness of bladder filling; cortical inhibition (suprapontine modulation) of reflex (unstable) bladder contractions; ability to consciously tighten the external sphincter to prevent incontinence; normal bladder growth; and motivation by the child to stay dry. The transitional phase of voiding refers to the period when children are acquiring bladder control. Girls typically acquire bladder control before boys, and bowel control typically is achieved before bladder control.

A common condition in children is **bladder–bowel dysfunction**. This term was coined by the American Urological Association Vesicoureteral Reflux Guidelines Committee and refers to disorders of bladder and/or bowel function. The previous term for this condition was dysfunctional elimination syndrome.

DIURNAL INCONTINENCE

Daytime incontinence not secondary to neurologic abnormalities is common in children. The most common cause of daytime incontinence is an **overactive bladder (urge incontinence)**. At age 5 yr, 95% have been dry during the day at some time and 92% are dry. At 7 yr, 96% are dry, although 15% have significant urgency at times. At 12 yr, 99% are dry during the day. Table 543-1 lists the causes of diurnal incontinence in children.

The history should assess the pattern of incontinence, including the frequency, the volume of urine lost during incontinent episodes, whether the incontinence is associated with urgency or giggling, whether it occurs after voiding, and whether the incontinence is continuous. The frequency of voiding and whether there is nocturnal enuresis, a strong, continuous urinary stream, or sensation of incomplete bladder emptying should be assessed. A diary of when the child voids and whether the child was wet or dry is helpful. Other urologic problems such as urinary tract infections (UTIs), vesicoureteral reflux, neurologic disorders, or a family history of duplication anomalies should be assessed. Bowel habits also should be evaluated, because incontinence is common in children with constipation and/or encopresis. Diurnal incontinence can occur in girls with a history of sexual abuse. Physical examination is directed at identifying signs of organic causes of incontinence: short stature, hypertension, enlarged kidneys and/or bladder, constipation, labial adhesion, ureteral ectopy, back or sacral anomalies (see Fig. 542-4 in Chapter 542), and neurologic abnormalities.

Assessment tools include urinalysis, with culture if indicated; bladder diary (recorded times and volumes voided, whether wet or dry); postvoid residual urine volume (generally obtained by bladder scan); and **Dysfunctional Voiding Symptom Score** (Fig. 543-1). An alternative to the Dysfunctional Voiding Symptom Score is the **Vancouver Nonneurogenic Lower Urinary Tract Dysfunction/Dysfunctional Elimination Syndrome** questionnaire. This questionnaire is a validated tool that consists of 14 questions scored on a 5-point Likert scale to assess lower urinary tract and bowel dysfunction. In most cases, a uroflow with or without electromyography (noninvasive assessment of urinary flow pattern and measurement of external sphincter activity) is indicated. Another item that may be useful in children older than age 5 yr is the **Pediatric Symptom Checklist (PSC)**. The Pediatric Symptom Checklist is a brief screening questionnaire consisting of 35 questions that is used by pediatricians and other health professionals to improve the recognition and treatment of psychosocial problems in children.

Bowel function should be assessed also. The Bristol Stool Form Score (Fig. 543-2) also should be recorded. In addition, the clinician should utilize the Rome III diagnostic criteria, which classify functional gastrointestinal disorders that do not have underlying structural or tissue-based causes. Children 4 yr of age or older are diagnosed as being

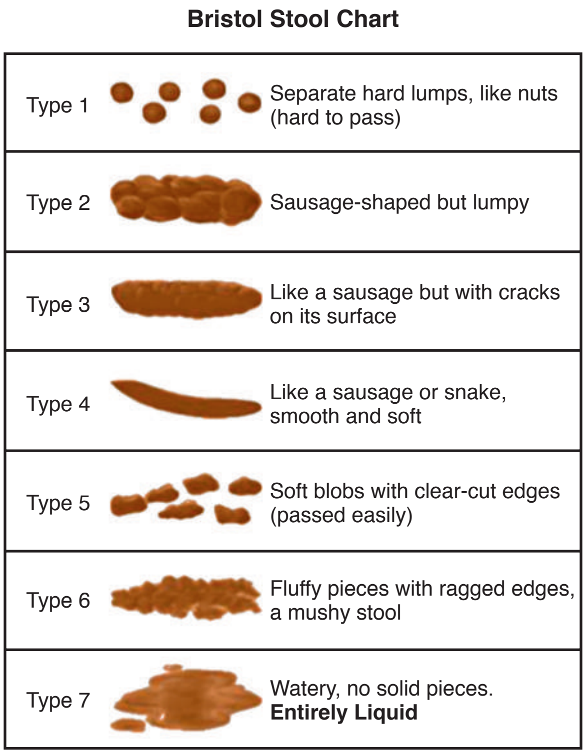

Figure 543-2 Bristol Stool Chart for evaluating bowel function.

constipated if they fulfill 2 or more of the following criteria over a period of 2 mo: 2 or fewer defecations in the toilet per week, at least 1 episode of fecal incontinence per week, a history of retentive posturing or excessive volitional stool retention, history of painful or hard bowel movements, presence of a large fecal mass in the rectum, and history of large-diameter stools that obstruct the toilet.

Imaging is performed in children who have significant physical findings, a family history of urinary tract anomalies or UTIs, and those who do not respond to therapy appropriately. A renal ultrasonogram with or without a **voiding cystourethrogram** is indicated. Urodynamics should be performed if there is evidence of neurologic disease and may be helpful if empirical therapy is ineffective. If there is any evidence of a neurologic disorder, an MRI of the lower spine should be obtained.

OVERACTIVE BLADDER (DIURNAL URGE SYNDROME)

Children with an overactive bladder typically exhibit urinary frequency, urgency, and urge incontinence. Often a girl will squat down on her foot to try to prevent incontinence (termed *Vincent's curtsy*). The bladder in these children is functionally, but not anatomically, smaller than normal and exhibits strong uninhibited contractions. Approximately 25% of children with nocturnal enuresis also have symptoms of an overactive bladder. Many children indicate they do not feel the need to urinate, even just before they are incontinent. In girls, a history of recurrent UTI is common, but incontinence can persist long after infections are brought under control. It is not clear if the voiding dysfunction is a sequela of the UTIs or if the voiding dysfunction predisposes to recurrent UTIs. In girls, voiding cystourethrography often shows a dilated urethra ("spinning-top deformity," Fig. 543-3) and narrowed bladder neck with bladder wall hypertrophy. The urethral finding results from inadequate relaxation of the external

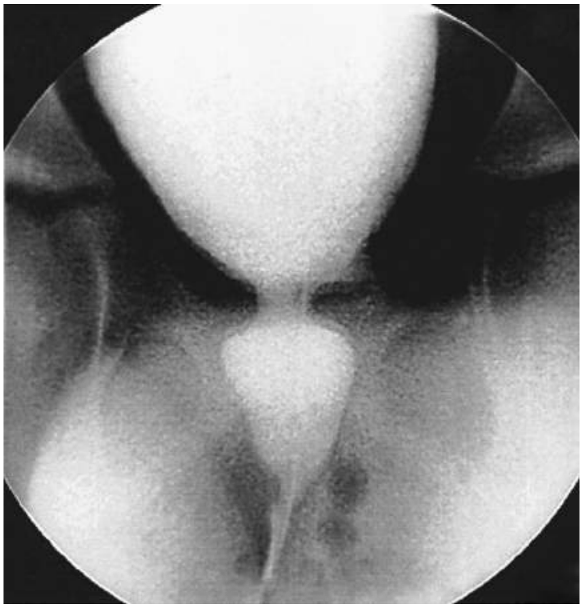

Figure 543-3 **Spinning-top deformity.** Voiding cystourethrogram demonstrating dilation of the urethra with distal urethral narrowing and contraction of the bladder neck.

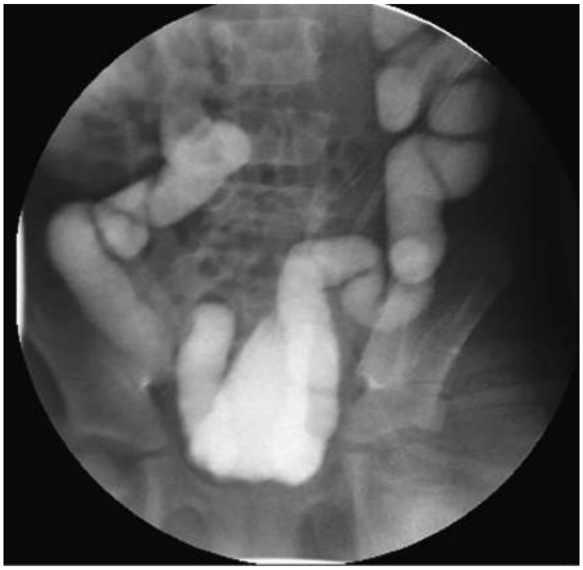

Figure 543-4 Voiding cystourethrogram demonstrating severe bladder trabeculation and vesicoureteral reflux in a 12 yr old boy with Hinman syndrome. The patient presented with day and night incontinence, had chronic renal failure, and underwent kidney transplantation.

urinary sphincter. Constipation is common and should be treated, particularly with any child with Bristol Stool Score 1 or 2.

The overactive bladder nearly always resolves, but the time to resolution is highly variable, sometimes not until the teenage years. Initial therapy is timed voiding, every 1.5-2.0 hr. Treatment of constipation and UTIs is important. Another treatment is biofeedback, in which children are taught pelvic floor exercises **(Kegel exercises)**, because there is evidence that daily performance of these exercises can reduce or eliminate unstable bladder contractions. Biofeedback often includes participation with animated computer games. Biofeedback also may include periodic uroflow studies with sphincter electromyography to be certain that the pelvic floor relaxes during voiding, and assessment of postvoid residual urine volume by sonography. Anticholinergic therapy with oxybutynin chloride, hyoscyamine, or tolterodine reduces bladder overactivity and may help the child achieve dryness. Treatment with an α-adrenergic blocker such as terazosin or doxazosin can aid in bladder emptying by promoting bladder neck relaxation; α-adrenergic blockers also have mild anticholinergic properties. If pharmacologic therapy is successful, the dosage should be tapered periodically to determine its continued need. Children who do not respond to therapy should be evaluated urodynamically to rule out other possible forms of bladder or sphincter dysfunction. In refractory cases, sacral nerve stimulation (InterStim) is a surgical procedure that has shown promise.

If the child has constipation based on the criteria described above, treatment generally is initiated with polyethylene glycol powder, which has been shown to be safe in children and generally more effective than other laxative preparations.

NONNEUROGENIC NEUROGENIC BLADDER (HINMAN SYNDROME)

Hinman syndrome is a very serious but uncommon disorder involving failure of the external sphincter to relax during voiding in children without neurologic abnormalities. Children with this syndrome, also called **nonneurogenic neurogenic bladder**, typically exhibit a staccato stream, day and night wetting, recurrent UTIs, constipation, and encopresis. Evaluation of affected children often reveals vesicoureteral reflux, a trabeculated bladder, and a decreased urinary flow rate with an intermittent pattern (Fig. 543-4). In severe cases, hydronephrosis, renal insufficiency, and end-stage renal disease can occur. The pathogenesis of this syndrome is thought to involve learning abnormal voiding habits during toilet training; the syndrome is rarely seen in infants. Urodynamic studies and magnetic resonance imaging of the spine are indicated to rule out a neurologic cause for the bladder dysfunction.

The treatment usually is complex and can include anticholinergic and α-adrenergic blocker therapy, timed voiding, treatment of constipation, behavioral modification, and encouragement of relaxation during voiding. Biofeedback has been used successfully in older children to teach relaxation of the external sphincter. In some cases botulinum toxin (Botox) injection into the external sphincter can provide temporary sphincteric paralysis and thereby reduce outlet resistance. In severe cases, intermittent catheterization is necessary to ensure bladder emptying. In selected patients, external urinary diversion is necessary to protect the upper urinary tract. These children require long-term treatment and careful follow-up.

INFREQUENT VOIDING (UNDERACTIVE BLADDER)

Infrequent voiding is a common disorder of micturition, usually associated with UTIs. Affected children, usually girls, void only twice a day rather than the normal 4-7 times. With bladder overdistention and prolonged retention of urine, bacterial growth can lead to recurrent UTIs. Some of these children are constipated. Some also have occasional episodes of incontinence from overflow or urgency. The disorder is behavioral. If the child has UTIs, treatment includes antibacterial prophylaxis and encouragement of frequent voiding and complete emptying of the bladder by double voiding until a normal pattern of micturition is re-established.

VAGINAL VOIDING

In girls with vaginal voiding, incontinence typically occurs after urination after the girl stands up. Usually the volume of urine is 5-10 mL. One of the most common causes is labial adhesion (Fig. 543-5). This lesion, typically seen in young girls, can be managed either by topical application of estrogen cream to the adhesion or lysis in the office. Some girls experience vaginal voiding because they do not separate their legs widely during urination. These girls either are overweight

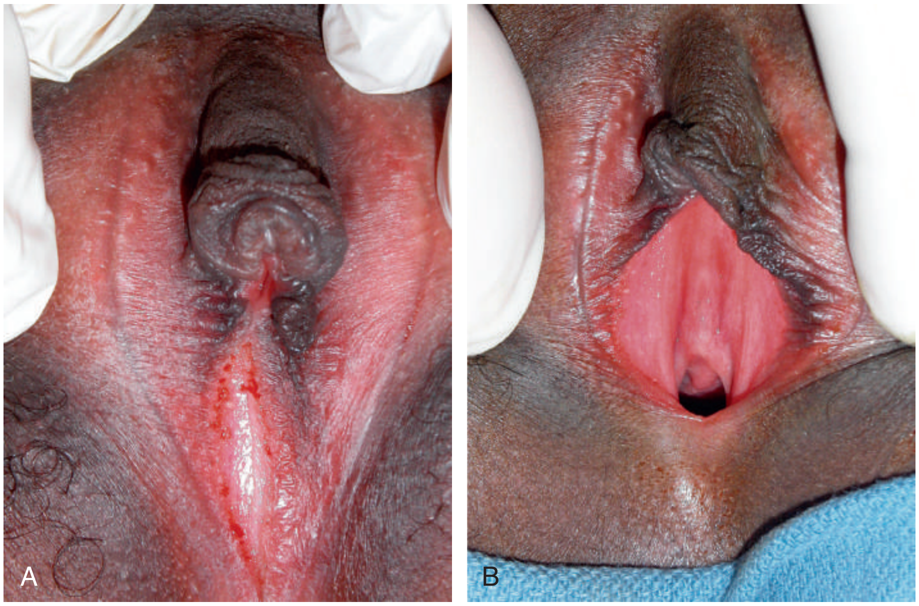

Figure 543-5 **A,** Labial adhesion. Note the inability to visualize the urethral meatus and vagina. **B,** Normal female external genitalia following lysis of labial adhesion.

or do not pull their underwear down to their ankles when they urinate. Management involves encouraging the girl to separate the legs as widely as possible during urination. The most effective way to do this is to have the child sit backward on the toilet seat during micturition.

OTHER CAUSES OF INCONTINENCE IN GIRLS

Ureteral ectopia, usually associated with a duplicated collecting system in girls, refers to a ureter that drains outside the bladder, often into the vagina or distal urethra. It can produce urinary incontinence characterized by constant urinary dripping all day, even though the child voids regularly. Sometimes the urine production from the renal segment drained by the ectopic ureter is small, and urinary drainage is confused with watery vaginal discharge. Children with a history of vaginal discharge or incontinence and an abnormal voiding pattern require careful study. The ectopic orifice usually is difficult to find. On ultrasonography or intravenous urography, one may suspect duplication of the collecting system (Fig. 543-6), but the upper collecting system drained by the ectopic ureter usually has poor or delayed function. CT scanning of the kidneys or an MR urogram should demonstrate subtle duplication anomalies. Examination under anesthesia for an ectopic ureteral orifice in the vestibule or the vagina may be necessary (Fig. 543-7). The treatment in these cases is either partial nephrectomy, with removal of the upper pole segment of the duplicated kidney and its ureter down to the pelvic brim, or ipsilateral ureteroureterostomy, in which the upper pole ectopic ureter is anastomosed to the normally positioned lower pole ureter. These procedures often are performed by minimally invasive laparoscopy with or without robotic assistance.

Giggle incontinence typically affects girls 7-15 yr of age. The incontinence occurs suddenly during giggling, and the entire bladder volume is lost. The pathogenesis is thought to be sudden relaxation of the urinary sphincter. Anticholinergic medication and timed voiding occasionally are effective. The most effective treatment is low-dose methylphenidate.

Total incontinence in girls may be secondary to **epispadias** (see Fig. 541-2 in Chapter 541). This condition, which affects only 1 in 480,000 females, is characterized by separation of the pubic symphysis, separation of the right and left sides of the clitoris, and a patulous urethra. Treatment is bladder neck reconstruction or placement of an artificial urinary sphincter to repair the incompetent urethra.

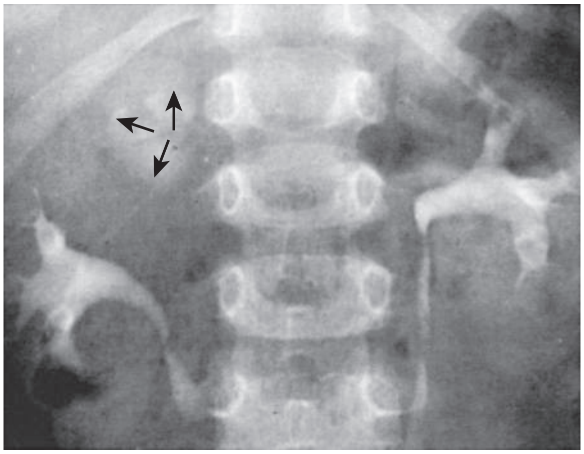

Figure 543-6 **Duplication of the right collecting system with ectopic ureter.** Excretory urogram in a girl presenting with a normal voiding pattern and constant urinary dribbling. The left kidney is normal, and the right side, well visualized, is the lower collecting system of a duplicated kidney. On the upper pole opposite the 1st and 2nd vertebral bodies, note the accumulation of contrast material corresponding with a poorly functioning upper pole drained by a ureter opening in the vestibule.

A short, incompetent urethra may be associated with certain urogenital sinus malformations. The diagnosis of these malformations requires a high index of suspicion and a careful physical examination of all incontinent girls. In these cases, urethral and vaginal reconstruction often restores continence.

VOIDING DISORDERS WITHOUT INCONTINENCE

Some children have abrupt onset of severe urinary frequency, voiding as often as every 10-15 min during the day, without dysuria, UTI, daytime incontinence, or nocturia. The most common age for these symptoms to occur is 4-6 yr, after the child is toilet trained, and the vast majority are boys. This condition is termed the **daytime frequency syndrome of childhood** or **pollakiuria**. The condition is functional;

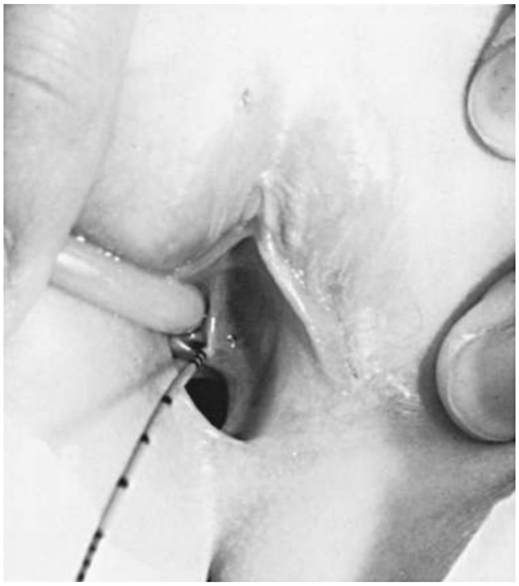

Figure 543-7 This photograph shows an ectopic ureter entering the vestibule next to the urethral meatus. The thin ureteral catheter with transverse marks has been introduced into this ectopic ureter. This girl had a normal voiding pattern and constant urinary dribbling.

Table 543-2	Nocturnal Enuresis
CAUSES	
Delayed maturation of the cortical mechanisms that allow voluntary control of the micturition reflex	
Defective sleep arousal	
Reduced antidiuretic hormone production at night, resulting in an increased urine output (nocturnal polyuria)	
Genetic factors, with chromosomes 12 and 13q the likely sites of the gene for enuresis	
Bladder factors (lack of inhibition, reduced capacity, overactive)	
Constipation	
Organic factors, such as urinary tract infection or obstructive uropathy	
Sleep disorders	
Sleep disordered breathing secondary to enlarged adenoids	
Psychologic factors more often implicated in secondary enuresis	
OTHER FEATURES	
Enuresis can occur in any stage of sleep (but usually non–rapid eye movement sleep)	
All children are most difficult to arouse in the first third of the night and easiest to awaken in the last third, but enuretic children are more difficult to arouse than those with normal bladder control	
Enuretic children often are described as "soaking the bed"	
Family history in enuretic children often positive for enuresis	
Risk increased with developmental delay, attention-deficit/hyperactivity disorder, autism spectrum disorders	

no anatomic problem is detected. Often the symptoms occur just before a child starts kindergarten or if the child is having emotional family stress-related problems. These children should be checked for UTIs, and the clinician should ascertain that the child is emptying the bladder satisfactorily. Occasionally, pinworms cause these symptoms. The condition is self-limited, and symptoms generally resolve within 2-3 mo. Anticholinergic therapy rarely is effective.

Some children have the **dysuria-hematuria syndrome**, in which the child has dysuria without UTI but with microscopic or gross hematuria. This condition affects children who are toilet-trained and is often secondary to hypercalciuria. A 24-hr urine sample should be obtained and calcium and creatinine excretion assessed. A 24-hr calcium excretion of >4 mg/kg is abnormal and deserves treatment with thiazides, because some of these children are at risk for urolithiasis.

NOCTURNAL ENURESIS

By 5 yr of age, 90-95% of children are nearly completely continent during the day, and 80-85% are continent at night. Nocturnal enuresis refers to the occurrence of involuntary voiding at night after 5 yr, the age when volitional control of micturition is expected. Enuresis may be primary (estimated 75-90% of children with enuresis; nocturnal urinary control never achieved) or secondary (10-25%; the child was dry at night for at least a few months and then enuresis developed). In addition, 75% of children with enuresis are wet only at night, and 25% are incontinent day and night. This distinction is important, because children with both forms are more likely to have an abnormality of the urinary tract. **Monosymptomatic enuresis** is more common than non-monosymptomatic enuresis (associated urgency, hesitancy, frequency, day time incontinence).

Epidemiology

Approximately 60% of children with nocturnal enuresis are boys. Family history is positive in 50% of cases. Although primary nocturnal enuresis may be polygenetic, candidate genes have been localized to chromosomes 12 and 13. If one parent was enuretic, each child has a 44% risk of enuresis; if both parents were enuretic, each child has a 77% likelihood of enuresis. Nocturnal enuresis without overt daytime voiding symptoms affects up to 20% of children at the age of 5 yr; it ceases spontaneously in approximately 15% of involved children every year thereafter. Its frequency among adults is <1%.

Pathogenesis

The pathogenesis of nocturnal enuresis (normal daytime voiding habits) is multifactorial (Table 543-2).

Clinical Manifestations and Diagnosis

A careful history should be obtained, especially with respect to fluid intake at night and pattern of nocturnal enuresis. Children with diabetes insipidus (see Chapter 558), diabetes mellitus (see Chapter 589), and chronic renal disease (see Chapter 535) can have a high obligatory urinary output and a compensatory polydipsia. The family should be asked whether the child snores loudly at night. A complete physical examination should include palpation of the abdomen and rectal examination after voiding to assess the possibility of a chronically distended bladder. The child with nocturnal enuresis should be examined carefully for neurologic and spinal abnormalities. There is an increased incidence of bacteriuria in enuretic girls, and, if found, it should be investigated and treated (see Chapter 538), although this does not always lead to resolution of bedwetting. A urine sample should be obtained after an overnight fast and evaluated for specific gravity or osmolality to exclude polyuria as a cause of frequency and incontinence and to ascertain that the concentrating ability is normal. The absence of glycosuria should be confirmed. If there are no daytime symptoms, the physical examination and urinalysis are normal, and the urine culture is negative, further evaluation for urinary tract pathology generally is not warranted. A renal ultrasonogram is reasonable in an older child with enuresis or in children who do not respond appropriately to therapy.

Treatment

The best approach to treatment is to reassure the child and parents that the condition is self-limited and to avoid punitive measures that can affect the child's psychologic development adversely. Fluid intake should be restricted to 2 oz after 6 or 7 PM. The parents should be certain that the child voids at bedtime. Avoiding extraneous sugar and caffeine after 4 PM also is beneficial. If the child snores and the adenoids are enlarged, referral to an otolaryngologist should be considered, because adenoidectomy can cure the enuresis.

Active treatment should be avoided in children younger than 6 yr of age, because enuresis is extremely common in younger children. Treatment is more likely to be successful in children approaching puberty compared with younger children. In addition, treatment is most likely to be effective in children who are motivated to stay dry. Treatment should be viewed as a facilitator that requires active participation by the child (e.g., a coach and an athlete).

The simplest initial measure is **motivational therapy** and includes a star chart for dry nights. Waking children a few hours after they go to sleep to have them void often allows them to awaken dry, although this measure is not curative. Some have recommended that children try holding their urine for longer periods during the day, but there is no evidence that this approach is beneficial. **Conditioning therapy** involves use of a loud auditory or vibratory alarm attached to a moisture sensor in the underwear. The alarm sounds when voiding occurs and is intended to awaken children and alert them to void. This form of therapy has a reported success of 30-60%, although the relapse rate is significant. Often the auditory alarm wakes up other family members and not the enuretic child; persistent use of the alarm for several months often is necessary to determine whether this treatment is effective. Conditioning therapy tends to be most effective in older children. Another form of therapy to which some children respond is self-hypnosis. The primary role of psychologic therapy is to help the child deal with enuresis psychologically and help motivate the child to void at night if he or she awakens with a full bladder.

Pharmacologic therapy is intended to treat the symptom of enuresis and thus is regarded as second line and is not curative. Direct comparisons of the bell and bed with pharmacologic therapy favor the former because of lower relapse rates, although initial response rates are equivalent.

One form of treatment is **desmopressin acetate**, a synthetic analog of antidiuretic hormone that reduces urine production overnight. This medication is FDA-approved and is available as a tablet, with a dosage of 0.2-0.6 mg at bedtime. In the past a nasal spray was used, but some children experienced hyponatremia and convulsions with this formulation and the nasal spray is no longer recommended for nocturnal enuresis. Hyponatremia has not been reported in children using the oral tablets. Fluid restriction at night is important, and the drug should not be used if the child has a systemic illness with vomiting or diarrhea or if the child has polydipsia. Desmopressin acetate is effective in as many as 40% of children. If effective, it should be used for 3-6 mo, and then an attempt should be made to taper the dosage. If tapering results in recurrent enuresis, the child should return to the higher dosage. Few adverse events have been reported with the long-term use of desmopressin acetate.

For therapy-resistant enuresis or children with symptoms of an overactive bladder, **anticholinergic therapy** is indicated. Oxybutynin 5 mg or tolterodine 2 mg at bedtime often are prescribed. If the medication is ineffective, the dosage may be doubled. The clinician should monitor for constipation as a potential side effect.

A third-line treatment is **imipramine**, which is a tricyclic antidepressant. This medication has mild anticholinergic and α-adrenergic effects, reduces urine output slightly, and also might alter the sleep pattern. The dosage of imipramine is 25 mg in children age 6-8 yr, 50 mg in children age 9-12 yr, and 75 mg in teenagers. Reported success rates are 30-60%. Side effects include anxiety, insomnia, and dry mouth, and heart rhythm may be affected. If there is any history of palpitations or syncope in the child, or sudden cardiac death or unstable arrhythmia in the family, long QT syndrome in the patient needs to be excluded. The drug is one of the most common causes of poisoning by prescription medication in younger siblings.

In unsuccessful cases, combining therapies often is effective. Alarm therapy plus desmopressin is more successful than either alone. The combination of oxybutynin chloride and desmopressin is more successful than either alone. Desmopressin and imipramine also may be combined.

Chapter 544

Anomalies of the Penis and Urethra

Jack S. Elder

HYPOSPADIAS

Hypospadias is a urethral opening on the ventral surface of the penile shaft affecting 1 in 250 male newborns. Typically an isolated defect, but its incidence is increased in disorders of sex differentiation, anorectal malformation, and congenital heart disease. Usually there is incomplete development of the prepuce, called a **dorsal hood**, in which the foreskin is on the sides and dorsal aspect of the penile shaft and deficient or absent ventrally. Some boys with hypospadias, particularly those with proximal hypospadias, have **chordee**, in which there is ventral penile curvature during erection. The incidence of hypospadias appears to be increasing, possibly because of in utero exposure to estrogenic or antiandrogenic endocrine-disrupting chemicals (e.g., polychlorobiphenyls, phytoestrogens).

Clinical Manifestations

Hypospadias is classified according to the position of the urethral meatus after taking into account whether chordee is present (Fig. 544-1). The deformity is described as glanular (on the glans penis), coronal, subcoronal, midpenile, penoscrotal, scrotal, or perineal. Approximately 65% of cases are distal, 25% are subcoronal or midpenile, and 10% are proximal. In the most severe cases, the scrotum is bifid and sometimes there is moderate penoscrotal transposition. As many as 10% of affected boys have a **megameatal variant**, in which the foreskin is developed normally (megameatus intact prepuce variant), and there is either glanular or subcoronal hypospadias with a “fish mouth” meatus. These cases might not be diagnosed until after a circumcision is performed.

Approximately 10% of boys with hypospadias have an undescended testis; inguinal hernias also are common. In the newborn, the differential diagnosis of midpenile or proximal hypospadias associated with an undescended testis should include forms of a disorder of sex development, particularly mixed gonadal dysgenesis, partial androgen insensitivity, true hermaphroditism, and congenital adrenal hyperplasia in a female (see Chapter 576). In the latter situation, neither gonad would be palpable. A karyotype should be obtained in patients with midpenile or proximal hypospadias and cryptorchidism (see Chapter 588). In boys with penoscrotal hypospadias, a voiding cystourethrogram should be considered because 5-10% of these children have a dilated prostatic utricle, which is a remnant of the müllerian system (see Chapter 554). The incidence of upper urinary tract abnormalities is low unless there are abnormalities of other organ systems.

Complications of untreated hypospadias include deformity of the urinary stream, typically ventral deflection or severe splaying; sexual dysfunction secondary to penile curvature; infertility if the urethral meatus is proximal; meatal stenosis (congenital), which is uncommon; and cosmetic appearance. The goal of hypospadias surgery is to correct the functional and cosmetic deformities. Whereas hypospadias repair is recommended for all boys with midpenile and proximal hypospadias, some boys with distal hypospadias have no functional abnormality and do not need any surgical correction.

Treatment

Management begins in the newborn period. Circumcision should be avoided, because the foreskin often is used in the repair in most cases. The ideal age for repair in a healthy infant is 6-12 mo, because the risk of general anesthesia at this age is similar to older children; penile growth over the next several years is slow; the child does not remember the surgical procedure; and postoperative analgesic needs are less than

Figure 544-1 Varying forms of hypospadias. **A,** Glanular hypospadias. **B,** Subcoronal hypospadias. Note the dorsal hood of foreskin. **C,** Penoscrotal hypospadias with chordee. **D,** Perineal hypospadias with chordee and partial penoscrotal transposition. **E,** Megameatal variant of hypospadias diagnosed following circumcision; note absence of hooded foreskin. **F,** Complete penoscrotal transposition with scrotal hypospadias.

in older children. With the exception of proximal hypospadias, virtually all cases are repaired in a single operation on an ambulatory basis. The most common repair involves tubularization of the urethral plate distal to the urethral meatus, with coverage by a vascularized flap from the foreskin, termed a *tubularized incised plate* repair. Proximal cases might require a 2-stage repair. The complication rate is low: 5% for distal hypospadias, 10% for midpenile hypospadias, and 20% for proximal hypospadias. The most common complications include urethrocutaneous fistula and meatal stenosis. Other complications include a deformed urinary stream, persistent penile curvature, and dehiscence of the hypospadias repair. Treatment of these complications generally is straightforward. In complex cases, a buccal mucosa graft is used to create urethral mucosa. Repair of hypospadias is a technically demanding operation and should be performed by a surgeon with specialty training in pediatric urology and extensive experience.

CHORDEE WITHOUT HYPOSPADIAS

In some boys there is mild or moderate ventral penile curvature **(chordee)** and incomplete development of the foreskin **(dorsal hood)**, but the urethral meatus is at the tip of the glans (Fig. 544-2). In most of these boys, the urethra is normal but there is insufficient ventral penile skin or prominent, inelastic ventral bands of dartos fascia that prevent a straight erection. In some cases, the urethra is hypoplastic, and a formal urethroplasty is necessary for repair. The only sign of this anomaly in the neonate may be the hooded foreskin, and delayed repair under general anesthesia at 6 mo of age is recommended.

PHIMOSIS AND PARAPHIMOSIS

Phimosis refers to the inability to retract the prepuce. At birth, phimosis is physiologic. Over time, the adhesions between the prepuce and glans lyse and the distal phimotic ring loosens. In 80% of uncircumcised boys the prepuce becomes retractable by 3 yr of age. Accumulation of epithelial debris under the infant's prepuce is physiologic and does not mandate circumcision. In older boys, phimosis may be physiologic, may be pathologic from inflammation and scarring at the tip of the foreskin (Fig. 544-3), or occurs after circumcision. The prepuce might have been retracted forcefully on 1 or 2 occasions in the past, which can result in a cicatricial scar that prevents subsequent retraction of the foreskin. In boys with persistent physiologic or pathologic phimosis, application of corticosteroid cream to the foreskin 3 times daily for 1 mo loosens the phimotic ring in two-thirds of cases. If there is ballooning of the foreskin during voiding or phimosis beyond 10 yr of age and topical corticosteroid therapy is ineffective, circumcision is recommended.

Paraphimosis occurs when the foreskin is retracted proximal to the coronal sulcus and the prepuce cannot be pulled back over the glans

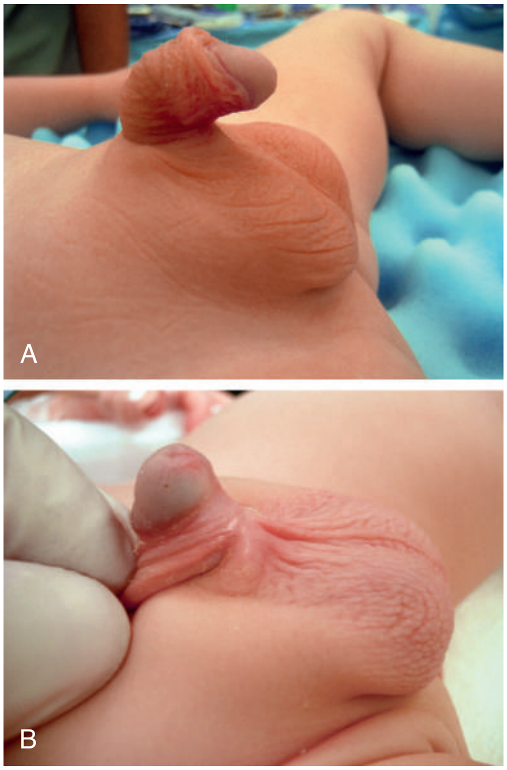

Figure 544-2 **A** and **B,** Two examples of chordee without hypospadias. Note hooded foreskin and normal location of urethral meatus.

Figure 544-3 **Balanitis xerotica obliterans.** Note whitish cicatricial plaque.

(Fig. 544-4). Painful venous stasis in the retracted foreskin results, with edema leading to severe pain and inability to reduce the foreskin (pull it back over the glans). Treatment includes lubricating the foreskin and glans and then simultaneously compressing the glans and placing distal traction on the foreskin to try to push the phimotic ring past the coronal sulcus. Topical application of granulated sugar has been reported to aid in reduction of edema by creation of an osmotic gradient, facilitating reduction of paraphimosis. In addition, injection of

Figure 544-4 **Paraphimosis.** The foreskin has been retracted proximal to the glans penis and has become markedly swollen secondary to venous congestion.

hyaluronidase into the edematous skin has been reported to result in immediate reduction in swelling. In rare cases, emergency circumcision under general anesthesia is necessary.

CIRCUMCISION

In the United States, circumcision usually is performed for cultural reasons. In 2012, a multidisciplinary task force of the American Academy of Pediatrics stated that evidence indicates that the health benefits of newborn male circumcision outweigh the risks and that the procedure's benefits justify access to this procedure for families who choose it. Specific benefits identified included prevention of urinary tract infections (UTIs), penile cancer, reducing the risk and transmission of some sexually transmitted infections, including HIV. The American College of Obstetricians and Gynecologists endorsed this policy statement. By contrast, European medical professional groups have been less likely to endorse this practice.

When performing a neonatal circumcision, local analgesia, such as a dorsal nerve block or application of EMLA (eutectic mixture of local anesthetics) cream (lidocaine 2.5% and prilocaine 2.5%) is recommended.

UTIs are 10-15 times more common in uncircumcised infant boys than in circumcised infants, with the urinary pathogens arising from bacteria that colonize the space between the prepuce and glans. The risk of febrile UTI (see Chapter 538) is highest between birth and 6 mo, but there is an increased risk of UTI until at least 5 yr of age. Many recommend circumcision in infants who are predisposed to UTI, such as those with congenital hydronephrosis and vesicoureteral reflux. Circumcision reduces the risk of sexually transmitted infections in adults (see Chapter 120), in particular HIV (see Chapter 276). There have been only a handful of reports of men who were circumcised at birth and subsequently acquired penile carcinoma, but in Scandinavian countries, where few men are circumcised and hygiene is good, the incidence of penile cancer is low.

Complications after neonatal circumcision include bleeding, wound infection, meatal stenosis, secondary phimosis, removal of insufficient foreskin, and fibrous penile adhesions (skin bridge; Fig. 544-5); 0.2-3.0% of patients undergo a subsequent operative procedure. Boys with a large hydrocele or hernia are at particular risk for secondary phimosis because the scrotal swelling tends to displace the penile shaft skin over the glans. Potentially serious complications include sepsis, amputation of the distal part of the glans, removal of an excessive amount of foreskin, and urethrocutaneous fistula. Circumcision should not be performed in neonates with hypospadias, chordee without hypospadias, or a dorsal hood deformity (relative contraindication) or in those with

Figure 544-5 Complications of circumcision. **A,** Denuded penile shaft. With local care, the penis healed and appeared normal. **B,** Midline epithelial inclusion cyst. **C,** Fibrous penile skin bridges.

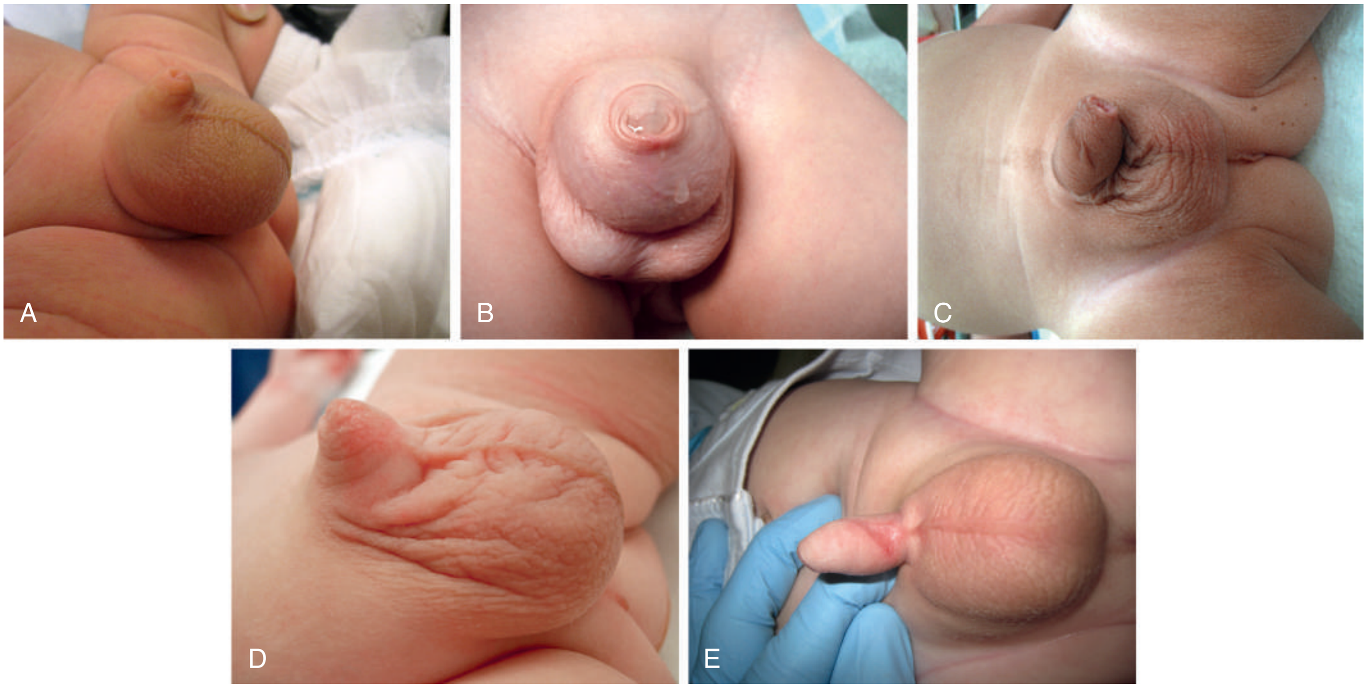

Figure 544-6 Examples of congenital deformities in which neonatal circumcision may be contraindicated. **A,** Hidden penis. **B,** Megaprepuce. **C,** Penile torsion to left side. **D,** Webbed penis; note scrotal attachment to penile shaft. **E,** Example of wandering raphe, with deviation of the median raphe to the left side. This finding may be an indication of penile torsion or hypospadias.

a small penis (Fig. 544-6). In boys with a **wandering raphe** (Fig. 544-6), in which the median raphe deviates to 1 side, there may be underlying penile torsion or hypospadias, and evaluation by a pediatric urologist is suggested before performing a circumcision.

PENILE TORSION

Penile torsion, a rotational defect of the penile shaft, usually occurs in a counterclockwise direction (to the left side: see Fig. 544-6). In most cases, penile development is normal, and the condition is unrecognized until circumcision is performed or the foreskin is retractable. In many cases the midline raphe of the penile shaft is deviated. Penile torsion also occurs in some boys with hypospadias. The defect has primarily cosmetic significance and correction is unnecessary if the rotation is <60 degrees from the midline.

INCONSPICUOUS PENIS

The term *inconspicuous penis* refers to a penis that appears to be small. A **webbed penis** is a condition in which the scrotal skin extends onto the ventral penile shaft. This deformity represents an abnormality of the attachment between the penis and scrotum. Although the deformity might appear mild, if a routine circumcision is performed, the penis can retract into the scrotum, resulting in secondary phimosis **(trapped penis)**. The concealed **(hidden or buried)** penis is a normally developed penis that is camouflaged by the suprapubic fat pad (Fig. 544-7). This anomaly may be congenital, iatrogenic after circumcision, or a result of obesity. Surgical correction is indicated for cosmetic reasons or if there is a functional abnormality with a splayed stream.

A **trapped penis** is an acquired form of inconspicuous penis and refers to a phallus that becomes embedded in the suprapubic fat pad after circumcision (Fig. 544-8). This deformity can occur after neonatal circumcision in an infant who has significant scrotal swelling from a large hydrocele or inguinal hernia or after routine circumcision in an infant with a webbed penis. This complication can predispose to UTIs and can cause urinary retention. Initial treatment of a trapped penis should include topical corticosteroid cream, which often loosens the phimotic ring. In some cases secondary repair is necessary at 6-9 mo.

MICROPENIS

Micropenis is defined as a normally formed penis that is at least 2.5 SD below the mean in size (Fig. 544-9). Typically, the ratio of the length

of the penile shaft to its circumference is normal. The pertinent measurement is the **stretched penile length**, which is measured by stretching the penis and measuring the distance from the penile base under the pubic symphysis to the tip of the glans. The mean length of the term newborn penis is 3.5 ± 0.7 cm and the diameter is 1.1 ± 0.2 cm. The diagnosis of micropenis is made if the stretched length is <1.9 cm.

Micropenis usually results from a hormonal abnormality that occurs after 14 wk of gestation. Common causes include hypogonadotropic hypogonadism, hypergonadotropic hypogonadism (primary testicular failure), and idiopathic micropenis. If growth hormone deficiency also is present, neonatal hypoglycemia can occur. The most common cause of micropenis is failure of the hypothalamus to produce an adequate amount of gonadotropin-releasing hormone, as typically occurs in Kallmann syndrome (see Chapter 583), Prader-Willi syndrome (see Chapter 108), and Lawrence-Moon-Bardet-Biedl syndrome. In some cases, there is growth hormone deficiency. Primary testicular failure can result from gonadal dysgenesis or rudimentary testes syndrome and also occurs in **Robinow syndrome** (characterized by hypoplastic genitalia, shortening of the forearms, frontal bossing, hypertelorism, wide palpebral fissures, short broad nose, long philtrum, small chin, brachydactyly, and a normal karyotype).

A pediatric endocrinologist, geneticist, and pediatric urologist should examine all children with these syndromes. **Evaluation** includes a karyotype, assessment of anterior pituitary function and testicular function, and MRI to determine the anatomic integrity of the hypothalamus and the anterior pituitary gland as well as the midline structure of the brain. One of the difficult questions is whether androgen therapy is essential during childhood, because androgenic stimulation of penile growth in a prepubertal boy can limit the growth potential of the penis in puberty. Studies of small groups of men with micropenis suggest that many, although not all, have satisfactory sexual function. Consequently, a decision for gender reassignment is made infrequently.

PRIAPISM

Priapism is a persistent penile erection at least 4 hr in duration that continues beyond, or is unrelated to, sexual stimulation. Typically, only the corpora cavernosa are affected. There are 3 subtypes:

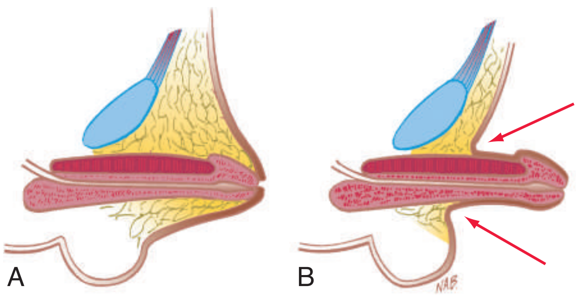

Figure 544-7 Concealed penis **(A),** which may be visualized by retracting skin lateral to penile shaft **(B).** *(From Wein AJ, Kavoussi LR, Novick AC, et al, editors:* Campbell-Walsh urology, *ed 9, Philadelphia, 2007, WB Saunders, Fig. 126-4, p. 2339.)*

Figure 544-9 Micropenis secondary to hypopituitarism in an 8-year-old boy. *(From Wein AJ, Kavoussi LR, Novick AC, et al, editors:* Campbell-Walsh urology, *ed 9, Philadelphia, 2007, WB Saunders, Fig. 126-5a, p. 2341.)*

Figure 544-8 **A,** Trapped (concealed) penis resulting from circumcision. **B,** Same patient after revision of circumcision. *(From Wein AJ, Kavoussi LR, Novick AC, et al, editors:* Campbell-Walsh urology, *ed 9, Philadelphia, 2007, WB Saunders, Fig. 126-2, p. 2340.)*

- Ischemic (venoocclusive, low-flow) priapism is characterized by little or no cavernous blood flow, and cavernous blood gases are hypoxic, hypercapnic, and acidotic. The corpora are rigid and tender to palpation.
- Nonischemic (arterial, high-flow) priapism is caused by unregulated cavernous arterial inflow. Typically, the penis is neither fully rigid nor painful. There is often a history of antecedent trauma resulting in a cavernous artery–corpora cavernosa fistula.
- Stuttering (intermittent) priapism is a recurrent form of ischemic priapism with painful erections with intervening periods of detumescence.

The most common cause of priapism in children is sickle cell disease, which is characterized by predominance of sickle cell hemoglobin (see Chapter 462.1). As many as 27.5% of children with sickle cell disease develop priapism. The priapism is generally related to a low-flow state, secondary to sickling of red blood cells within the sinusoids of the corpora cavernosa during normal erection, resulting in venous stasis. This situation results in decreased local oxygen tension and pH, which potentiates further stasis and sickling. Priapism typically occurs during sleep, when mild hypoventilatory acidosis depresses oxygen tension and pH in the corpora. There is typically significant corporal engorgement with sparing of the glans penis. If the spongiosum is involved, voiding may be impaired. Evaluation includes complete blood count and serum chemistry. If sickle cell status is unknown, hemoglobin electrophoresis should be performed. In some cases, corporal aspiration is performed to distinguish between a high-flow and low-flow state. Other causes of low-flow priapism include sildenafil ingestion and leukemia.

In priapism secondary to sickle cell disease, medical therapy includes exchange transfusion, intravenous hydration, alkalinization, pain management with morphine, and oxygen. The American Urological Association guideline on priapism also recommends concurrent intracavernous treatment beginning with corporal aspiration and irrigation with a sympathomimetic agent, such as phenylephrine. If priapism has been present >48 hr, ischemia and acidosis impair the intracavernous smooth muscle response to sympathomimetics. If irrigation and medical therapy are unsuccessful, a corporoglanular shunt should be considered. For stuttering priapism, administration of an oral α-adrenergic agent (pseudoephedrine) once or twice daily is first-line therapy. If this treatment is unsuccessful, an oral β-agonist (terbutaline) is recommended; a gonadotropin-releasing hormone analog plus flutamide is recommended as third-line therapy. Long-term follow-up of adults treated for sickle cell disease as children shows that satisfactory erectile function is inversely related to the patient's age at onset of priapism and duration of priapism.

Nonischemic (high-flow) priapism most commonly follows perineal trauma, such as a straddle injury, that results in laceration of the cavernous artery. Typically, the aspirated blood is bright red, and the aspirate is similar to arterial blood. Color Doppler ultrasonography often demonstrates the fistula. The priapism can spontaneously resolve. If it does not, angiographic embolization is indicated.

OTHER PENILE ANOMALIES

Agenesis of the penis affects approximately 1 in 10 million boys. The karyotype is almost always 46,XY, and the usual appearance is that of a well-developed scrotum with descended testes and an absent penile shaft. Upper urinary tract abnormalities are common. In most cases, gender reassignment is recommended in the newborn period. **Diphallia** ranges from a small accessory penis to complete duplication. **Lateral penile curvature** usually is caused by overgrowth or hypoplasia of a corporal (erectile) body and usually is congenital. Surgical repair is recommended at age 6-12 mo.

MEATAL STENOSIS

Meatal stenosis is a condition that almost always is acquired and occurs after neonatal circumcision. It probably results from severe inflammation of the denuded glans, and is difficult to prevent. If the meatus is pinpoint, boys void with a forceful, fine stream that goes a great distance. These boys can experience dysuria, frequency, hematuria, or a combination of these conditions, typically at age 3-8 yr. UTI is uncommon. Other boys have dorsal deflection of the urinary stream. Although the meatus may be small, hydronephrosis or voiding difficulty is extremely rare unless there is associated **balanitis xerotica obliterans** (see Fig. 544-3; chronic dermatitis of unknown etiology, generally involving the glans and prepuce, occasionally extending into the urethra). **Treatment** is meatoplasty, in which the urethral meatus is opened surgically; this procedure can be performed either under anesthesia as an outpatient or in the office using local anesthesia (EMLA cream) with or without sedation. Routine cystoscopy is unnecessary.

OTHER MALE URETHRAL ANOMALIES

Parameatal urethral cyst manifests as an asymptomatic small cyst on one side of the urethral meatus. Treatment is excision under anesthesia. **Congenital urethral fistula** is a rare deformity in which a fistula is present from the penile urethra. It usually is an isolated abnormality. Treatment is fistula closure. **Megalourethra** is a large urethra that usually is associated with abnormal development of the corpus spongiosum. This condition is most commonly associated with prune-belly syndrome (see Chapter 540). **Urethral duplication** is a rare condition in which the 2 urethral channels lie in the same sagittal plane. There are many variations with complete and incomplete urethral duplication. These boys often have a double stream. Most commonly the dorsal urethra is small and the ventral urethra is normal caliber. Treatment involves excision of the small urethra. **Urethral hypoplasia** is a rare condition in which the urethra is extremely small but patent. In some cases, a temporary cutaneous vesicostomy is necessary for satisfactory urinary drainage. Either gradual enlargement of the urethra or major urethroplasty is necessary. **Urethral atresia** refers to maldevelopment of the urethra and nearly always is fatal unless the urachus remains patent throughout gestation.

URETHRAL PROLAPSE (FEMALE)

Urethral prolapse is encountered predominantly in black girls 1-9 yr of age. The most common signs are bloody spotting on the underwear or diaper, although dysuria or perineal discomfort also can occur (Fig. 544-10). An inexperienced examiner can mistake the finding for sexual

abuse. The usual therapy consists of application of estrogen cream 2-3 times daily for 3-4 wk and sitz baths. Surgical excision and reapproximation of the mucosal edges is recommended for girls that fail medical therapy and is curative.

OTHER FEMALE URETHRAL LESIONS

Paraurethral cyst results from retained secretions in the Skene glands secondary to ductal obstruction (Fig. 544-11). These lesions are present at birth, and most regress in size during the 1st 4-8 wk, although occasionally incision and drainage is necessary. A **prolapsed ectopic ureterocele** appears as a cystic mass protruding from the urethra and is a presenting symptom in 10% of girls with a ureterocele, which is a cystic swelling of the terminal ureter (Fig. 544-12). Ultrasonography should be performed to visualize the upper urinary tracts to confirm the diagnosis. Usually, either the ureterocele is incised or an upper urinary tract reconstructive procedure is necessary.

Chapter 545

Disorders and Anomalies of the Scrotal Contents

Jack S. Elder

UNDESCENDED TESTIS (CRYPTORCHIDISM)

The absence of a palpable testis in the scrotum indicates that the testis is undescended, absent, or retractile.

Epidemiology

An undescended **(cryptorchid)** testis is the most common disorder of sexual differentiation in boys. At birth, approximately 4.5% of boys have an undescended testis. Because testicular descent occurs at 7-8 mo of gestation, 30% of premature male infants have an undescended testis; the incidence is 3.4% at term. The majority of congenital undescended testes descend spontaneously during the 1st 3 mo of life, and by 6 mo the incidence decreases to 0.8%. Spontaneous descent occurs secondary to a temporary testosterone surge during the 1st 2 mo, which also results in significant penile growth. If the testis has not descended by 4 mo, it will remain undescended. Cryptorchidism is bilateral in 10% of cases. There is some evidence that the incidence of cryptorchidism is increasing. Although cryptorchidism usually is considered to be congenital, some boys have a scrotal testis that "ascends" to a low inguinal position, and therefore requires an orchiopexy. In addition, 1-2% of neonatal and young boys undergoing hernia repair have secondary cryptorchidism.

Pathogenesis

The process of testicular descent is regulated by an interaction between hormonal and mechanical factors, including testosterone, dihydrotestosterone, müllerian-inhibiting factor, the gubernaculum, intraabdominal pressure, and the genitofemoral nerve. The testis develops at 7-8 wk of gestation. At 10-11 wk, the Leydig cells produce testosterone, which stimulates differentiation of the wolffian (mesonephric) duct into the epididymis, vas deferens, seminal vesicle, and ejaculatory duct. At 32-36 wk, the testis, which is anchored at the internal inguinal ring by the gubernaculum, begins its process of descent. The gubernaculum distends the inguinal canal and guides the testis into the scrotum. Following testicular descent, the patent processus vaginalis (hernia sac) normally involutes. A small percentage have Klinefelter syndrome or mutations in the insulin-like factor 3 receptor.

Clinical Manifestations

Undescended testes are classified as **abdominal** (nonpalpable), **peeping** (abdominal but can be pushed into the upper part of the inguinal canal), **inguinal, gliding** (can be pushed into the scrotum but retracts immediately to the pubic tubercle), and **ectopic** (superficial inguinal pouch or, rarely, perineal). Most undescended testes are palpable just distal to the inguinal canal over the pubic tubercle.

A **disorder of sex development** should be suspected in a newborn phenotypic male with bilateral nonpalpable testes, as the child could be a virilized girl with congenital adrenal hyperplasia (see Chapter 576). In a boy with midpenile or proximal hypospadias and a palpable undescended testis, disorder of sexual development is present in 15%, and the risk is 50% if the testis is nonpalpable.

The **consequences of cryptorchidism** include poor testicular growth, infertility, testicular malignancy, associated hernia, torsion of the cryptorchid testis, and the possible psychologic effects of an empty scrotum.

The undescended testis is normal at birth histologically, but pathologic changes can be demonstrated by 6-12 mo. Delayed germ cell maturation, reduction in germ cell number, hyalinization of the

seminiferous tubules, and reduced Leydig cell number are typical; these changes are progressive over time if the testis remains undescended. Similar, although less severe, changes are found in the contralateral descended testis after 4-7 yr. After treatment for a unilateral undescended testis, 85% of patients are fertile, which is slightly less than the 90% rate of fertility in an unselected population of men. In contrast, following bilateral orchiopexy, only 50-65% of patients are fertile.

The risk of a **germ cell malignancy** (see Chapter 503) developing in an undescended testis is 4 times higher than in the general population and is approximately 1 in 80 with a unilateral undescended testis and 1 in 40-50 for bilateral undescended testes. Testicular tumors are less common if the orchiopexy is performed before 10 yr of age, but they still occur, and adolescents should be instructed in testicular self-examination. The peak age for developing a testis tumor is 15-45 yr. The most common tumor developing in an undescended testis in an adolescent or adult is a **seminoma** (65%); after orchiopexy, nonseminomatous tumors represent only 65% of testis tumors. Orchiopexy seems to reduce the risk of seminoma. Whether early orchiopexy reduces the risk of developing cancer of the testis is controversial, but it is uncommon for testis tumors to occur if the orchiopexy performed before the age of 2 yr. The contralateral scrotal testis is not at increased risk for malignancy.

An indirect inguinal hernia usually accompanies a congenital undescended testis but rarely is symptomatic. Torsion and infarction of the cryptorchid testis also are uncommon but can occur because of excessive mobility of undescended testes. Consequently, inguinal pain and/or swelling in a boy with an undescended testis should raise the suspicion of an incarcerated hernia or testicular torsion of the undescended testis.

"Acquired" or **ascending undescended testes** occurs when a boy has a descended testis at birth, but during childhood, usually between 4-10 yr of age, the testis does not remain in the scrotum. Such boys often have a history of a retractile testis. With testicular ascent, on physical examination the testis often can be manipulated into the scrotum, but there is obvious tension on the spermatic cord. This condition is speculated to result from incomplete involution of the processus vaginalis, restricting spermatic cord growth, resulting in the testis gradually moving out of its scrotal position during a boy's somatic growth.

Retractile testes may be misdiagnosed as undescended testes. Boys older than age 1 yr often have a brisk cremasteric reflex, and if the child is anxious or ticklish during scrotal examination, the testis may be difficult to manipulate into the scrotum. Boys should be examined with their legs in a relaxed frogleg position, and if the testis can be manipulated into the scrotum comfortably, it is probably retractile. It should be monitored every 6-12 mo with follow-up physical examinations, because it can become an acquired undescended testis. Overall, as many as one-third of boys with a retractile testis develop an acquired undescended testis, and boys younger than 7 yr of age at diagnosis of a retractile testis are at greatest risk. Although definitive data are not available, it is generally thought that boys with a retractile testis are not at increased risk for infertility or malignancy.

Approximately 10% of undescended testes are **nonpalpable testis**. Of these, 50% are viable testes in the abdomen or high in the inguinal canal, and 50% are atrophic or absent, almost always in the scrotum, secondary to spermatic cord torsion in utero **(vanishing testis).** If the nonpalpable testis is abdominal, it will not descend after 3 mo of age. Although sonography often is performed to try to identify whether the testis is present, it rarely changes clinical management, because the abdominal testis and atrophic testis are not identified on sonography. As part of the ABIM Choosing Wisely campaign, in 2012 the American Urological Association recommended that inguinal/scrotal sonography not be performed routinely in boys with a nonpalpable testis, because it rarely alters the surgical management. However, inguinal/scrotal sonography might be beneficial in obese boys with a nonpalpable testis; in this clinical setting, the undescended testis often is nonpalpable, and an inguinal/scrotal sonogram can be beneficial in surgical planning. CT scanning is relatively accurate in demonstrating the presence of the testis, but the radiation exposure is significant. MRI is even more accurate, but the disadvantage is that general anesthesia is necessary in most young children. None of these imaging studies are 100% accurate and in general do not add significantly to clinical decision making by the pediatric urologist or pediatric surgeon. Consequently, its routine use is discouraged.

On **physical examination** of the scrotum, the child should be entirely undressed, to help him relax. The examiner should examine the patient's scrotum and inguinal canal using their dominant hand. The nondominant hand is positioned over the pubic tubercle and is pushed inferiorly toward the scrotum. The examiner's dominant hand is used to try to palpate the testis. If the testis is nonpalpable, the "soap test" often is useful; soap is applied to the inguinal canal and the examiner's hand, significantly reducing friction and facilitating identification of an inguinal testis. In addition, pulling on the scrotum can pull a high inguinal testis into a palpable position. One soft sign that a testis is absent is contralateral testicular hypertrophy, but this finding is not 100% diagnostic.

Treatment

The congenital undescended testis should be treated surgically by 9-15 mo of age. With anesthesia by a pediatric anesthesiologist, surgical correction at 6 mo is appropriate, because spontaneous descent of the testis will not occur after 4 mo of age. Most testes can be brought down to the scrotum with an orchiopexy, which involves an inguinal incision, mobilization of the testis and spermatic cord, and correction of an indirect inguinal hernia. The procedure is typically performed on an outpatient basis and has a success rate of 98%. In some boys with a testis that is close to the scrotum, a prescrotal orchiopexy can be performed. In this procedure, the entire operation is performed through an incision along the edge of the scrotum. Often the associated inguinal hernia also can be corrected with this incision. Advantages of this approach over the inguinal approach include shorter operative time and less postoperative discomfort.

In boys with a nonpalpable testis, diagnostic laparoscopy is performed in most centers. This procedure allows safe and rapid assessment of whether the testis is intraabdominal. In most cases, orchiopexy of the intraabdominal testis located immediately inside the internal inguinal ring is successful, but orchiectomy should be considered in more difficult cases or when the testis appears to be atrophic. A 2-stage orchiopexy sometimes is needed in boys with a high abdominal testis. Boys with abdominal testes are managed with laparoscopic techniques at many institutions. Testicular prostheses are available for older children and adolescents when the absence of the gonad in the scrotum might have an undesirable psychologic effect. The FDA has approved a saline testicular implant. Solid silicone "carving block" implants also are used (Fig. 545-1). Placement of testicular prostheses early in childhood is recommended for boys with anorchia (absence of both testes).

The American Urological Association released guidelines for the evaluation and treatment of boys with an undescended testis in 2014. Table 545-1 summarizes the primary statements.

SCROTAL SWELLING

Scrotal swelling may be acute or chronic and painful or painless. Abrupt onset of painful scrotal swelling necessitates prompt evaluation because some conditions, such as testicular torsion and incarcerated inguinal hernia, require emergency surgical management. Tables 545-2 and 545-3 show the differential diagnosis.

Clinical Manifestations

A detailed history is helpful in determining the cause of the swelling and includes onset of pain—with testicular torsion, the pain often is sudden in onset and may be associated with exercise or minor genital trauma; duration of pain; radiation of pain—inguinal discomfort is common with testicular torsion, inguinal hernia, or epididymitis, and associated flank pain can occur with passage of a ureteral calculus; previous episodes of similar pain, which are common in boys with intermittent testicular torsion or inguinal hernia; nausea and vomiting, which are associated with testicular torsion and inguinal hernia; and irritative urinary symptoms, such as dysuria, urgency, and frequency,

Table 545-1 American Urological Association Guidelines for Evaluation and Treatment of Boys with an Undescended Testis

DIAGNOSIS

Primary care providers should palpate testes for quality and position at each recommended well-child visit. (Standard)

Providers should refer infants with a history of cryptorchidism (detected at birth) who do not have spontaneous testicular descent by 6 mo (corrected for gestational age) to an appropriate surgical specialist for timely evaluation. (Standard)

Providers should refer boys with the possibility of newly diagnosed (acquired) cryptorchidism after 6 mo. (Standard)

Providers must immediately consult an appropriate specialist for all phenotypic male newborns with bilateral, nonpalpable testes for evaluation of a possible disorder of sex development (DSD). (Standard)

Providers should not perform ultrasound (US) or other imaging modalities in the evaluation of boys with cryptorchidism before referral because these studies rarely assist in decision making. (Standard)

Providers should assess the possibility of a disorder of sex development (DSD) when there is increasing severity of hypospadias with cryptorchidism. (Recommendation)

In boys with retractile testes, providers should monitor the position of the testes at least annually to monitor for secondary ascent. (Standard)

TREATMENT

Providers should not use hormonal therapy to induce testicular descent, since evidence shows low response rates and lack of evidence for long-term efficacy. (Standard)

In the absence of spontaneous testicular descent by 6 mo (corrected for gestational age), specialists should perform surgery within the next year. (Standard)

In prepubertal boys with nonpalpable testes, surgical specialists should perform examination under anesthesia to reassess for palpability of testes. If nonpalpable, surgical exploration and, if indicated, abdominal orchidopexy should be performed. (Standard)

In boys with a normal contralateral testis, surgical specialists may perform an orchiectomy (removal of the undescended testis) if a boy has a normal contralateral testis and either very short testicular vessels and vas deferens, dysmorphic or very hypoplastic testis, or postpubertal age. (Clinical Principle)

Providers should counsel boys with a history of cryptorchidism and/or monorchidism and their parents regarding potential long-term risks and provide education on infertility and cancer risk. (Clinical Principle)

*May be associated with discomfort.

which indicate a urinary tract infection that can cause epididymitis. Some boys report a recent history of scrotal trauma. There are multiple reports of familial testicular torsion. Boys with lower urinary tract pathology such as urethral stricture or neuropathic bladder may be prone to epididymitis.

Physical examination may be difficult in boys with a painful scrotum. Some have advocated performing a spermatic cord block or administering intravenous analgesia to facilitate the examination, but such measures usually are unnecessary. Scrotal wall erythema is common in testicular torsion, epididymitis, torsion of the appendix testis, and an incarcerated hernia. In boys with a normal cremasteric reflex, testicular torsion is unlikely. Absence of a cremasteric reflex is nondiagnostic.

Laboratory Findings and Diagnosis

Pertinent laboratory studies include a urinalysis and culture. A positive urinalysis suggests bacterial epididymitis. Serum studies are not helpful in establishing a diagnosis, unless a testicular malignancy is suspected. After initial evaluation, in boys with testicular pain color Doppler ultrasonography often is helpful in establishing the diagnosis, because it assesses whether testicular blood flow is normal, reduced, or increased (Fig. 545-2). If a hydrocele is present and the testis is nonpalpable, or if an abnormality of the testis is found, sonography also is indicated. Imaging studies are not 100% accurate; they should not be used to decide whether a boy with testicular pain should be referred for urologic evaluation.

Color Doppler ultrasonography allows assessment of testicular blood flow and testicular morphologic features. Accuracy is >95% if

the ultrasonographer is experienced and the patient is older than 2 yr old. A false-negative study (demonstrates normal testicular blood flow) can occur in a boy with testicular torsion if the degree of torsion is <360 degrees and the duration of torsion is short, because there may be continued testicular perfusion. In young boys, including neonates, blood flow may be difficult to demonstrate in 15% of normal testes.

TESTICULAR (SPERMATIC CORD) TORSION

Etiology

Testicular torsion requires prompt diagnosis and treatment to salvage the testis. Torsion is the most common cause of testicular pain in boys age 12 yr and older, and is uncommon before age 10 yr. It is caused by inadequate fixation of the testis within the scrotum, resulting from a redundant tunica vaginalis, allowing excessive mobility of the testis. The abnormal attachment is termed a *bell clapper deformity* and often is bilateral. Shortly after torsion occurs, venous congestion begins and subsequently arterial flow is interrupted. The likelihood of testis survival depends on the duration and severity of torsion. Following 4-6 hr of absent blood flow to the testis, irreversible loss of spermatogenesis can occur. Torsion may be familial in approximately 10% of males.

Diagnosis

Testicular torsion produces acute pain and swelling of the scrotum. On examination, the scrotum is swollen, and the testis is exquisitely tender and often difficult to examine. The cremasteric reflex nearly always is absent. The position (lie) of the testis is abnormal and there is often associated nausea and vomiting. The condition can be differentiated from an incarcerated hernia because swelling in the inguinal area typically is absent with torsion. If the pain duration is <4-6 hr, manual detorsion may be attempted. In 65% of cases the torsed testis rotates inward, so detorsion should be attempted in the opposite direction (e.g., the left testis is rotated clockwise). Successful manual detorsion results in dramatic pain relief.

Some adolescents experience *intermittent testicular torsion*. These boys report episodes of severe unilateral testicular pain that resolves spontaneously after 30-60 min. Treatment is elective bilateral scrotal orchiopexy (see Treatment).

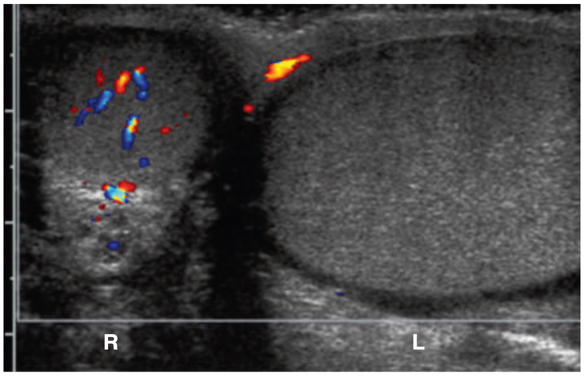

Figure 545-2 **Testicular torsion and axis change.** A color Doppler ultrasound in the transverse plane shows color flow in the right testicle. The right testicle is oval to circular, because it has been evaluated in the transverse plane. The left testicle is elongated as if it is in longitudinal plane. This axis change is the ultrasound equivalent of the worrisome clinical finding suggestive of torsion when accompanied by a history of sudden pain. Lack of color Doppler flow in the left testicle confirms a left testicular torsion. *(From Coley BD, editor:* Caffey's pediatric imaging, *ed 12, Philadelphia, Elsevier, 2013, Fig. 126-13, p. 1300).*

Treatment

Treatment is prompt surgical exploration and detorsion. If the testis is explored within 6 hr of torsion, up to 90% of the gonads survive. Testicular salvage decreases rapidly with a delay of >6 hr. If the degree of torsion is 360 degrees or less, the testis might have sufficient arterial flow to allow the gonad to survive, even after 24-48 hr. Following detorsion the testis is fixed in the scrotum with nonabsorbable sutures, termed *scrotal orchiopexy,* to prevent torsion in the future. The contralateral testis also should be fixed in the scrotum because the predisposing anatomic condition often is bilateral. If the testis appears nonviable, orchiectomy is performed (Fig. 545-3*A*). Some adolescents do not undergo prompt evaluation and treatment and present with "late phase testicular torsion," in which the spermatic cord contracts and the testis is high in the scrotum and nontender (Fig. 545-3*B*). Fertility is reduced in men who experience spermatic cord torsion in adolescence, irrespective of whether detorsion or orchiectomy is performed.

Spermatic cord torsion also can occur in the fetus or neonate. This condition results from incomplete attachment of the tunica vaginalis to the scrotal wall and is "extravaginal." When torsion occurs in utero, the baby usually is born with a large, firm, nontender testis. Usually the ipsilateral hemiscrotum is ecchymotic (Fig. 545-4). In these cases, the testis rarely is viable because torsion was a remote event. However, the contralateral testis is at increased risk for torsion until 1-2 mo beyond term. The pediatric urology community is divided regarding whether immediate exploration is necessary in a male newborn who has suspected testicular torsion at birth, but if observation is recommended, the family needs to be counseled regarding the risk of contralateral spermatic cord torsion. On the other hand, if the initial exam is normal, and the newborn subsequently develops scrotal swelling and erythema, and imaging is consistent with spermatic cord torsion, emergency scrotal exploration is indicated.

TORSION OF THE APPENDIX TESTIS

Torsion of the appendix testis is the most common cause of testicular pain in boys 2-10 yr but is rare in adolescents. The appendix testis is a stalk-like structure that is a vestigial embryonic remnant of the müllerian (paramesonephric) ductal system that is attached to the upper

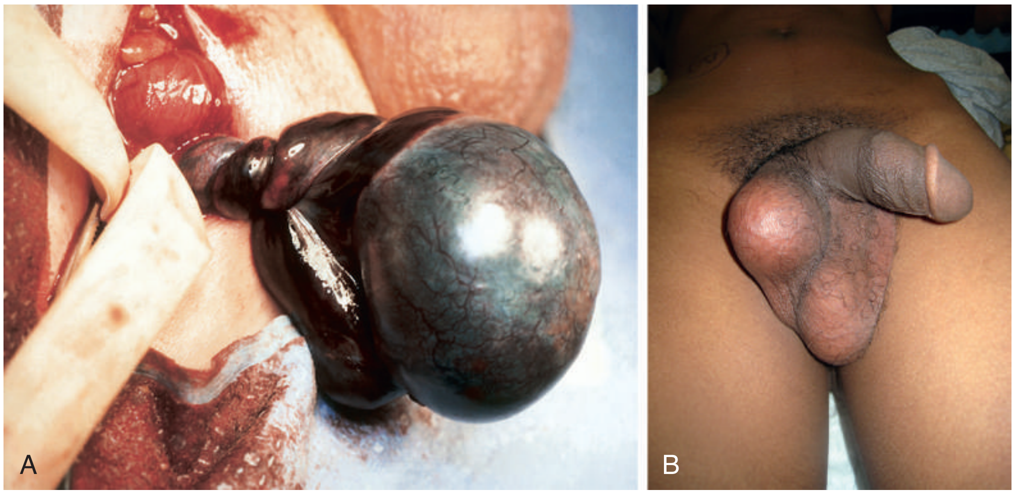

Figure 545-3 **A,** Left testicular torsion in adolescent with acute scrotum; the testis is necrotic. **B,** "Late-phase torsion" in an adolescent with severe testicular pain 1 mo previously. Note absence of inflammation and high position of testis in scrotum.

Figure 545-4 **A** and **B,** Right testicular torsion in a newborn. The right hemiscrotum is darker, and the testis was indurated and enlarged.

pole of the testis. When it undergoes torsion, progressive inflammation and swelling of the testis and epididymis occurs, resulting in testicular pain and scrotal erythema. The onset of pain usually is gradual. Palpation of the testis usually reveals a 3-5 mm tender indurated mass on the upper pole (Fig. 545-5*A*). In some cases, the appendage that has undergone torsion may be visible through the scrotal skin, in the "blue dot" sign. In some boys, distinguishing torsion of the appendix from testicular torsion is difficult. In such cases, a testicular flow scan or color Doppler ultrasonography is useful because testicular blood flow should be normal or increased. In such cases, the radiologist often recognizes epididymal enlargement and makes the diagnosis of epididymitis, reflecting the inflammatory reaction (Fig. 545-5*B*).

The natural history of torsion of the appendix testis is for the inflammation to resolve in 3-10 days. Nonoperative treatment is recommended, including bed rest for 24 hr and analgesia with nonsteroidal antiinflammatory medication for 5 days. If the diagnosis is uncertain, scrotal exploration is recommended.

EPIDIDYMITIS

Acute inflammation of the epididymis is an ascending retrograde infection from the urethra, through the vas into the epididymis. This condition causes acute scrotal pain, erythema, and swelling. It is rare before puberty and should raise the question of a congenital abnormality of the wolffian duct, such as an ectopic ureter entering the vas. In younger boys, the responsible organism is often *Escherichia coli* (see Chapter 200). After puberty, bacterial epididymitis becomes progressively more common and is the principal cause of acute painful scrotal swelling in young sexually active men. Urinalysis usually reveals pyuria. Epididymitis can be infectious (usually gonococcus or *Chlamydia*; see Chapters 192 and 226), but often the organism remains undetermined. Additional etiologies include familial Mediterranean fever, enterovirus, and adenoviruses. Treatment consists of bed rest and antibiotics as indicated. Differentiation from torsion can be difficult, and surgical exploration may be required in children.

Henoch-Schönlein purpura (see Chapter 484) is a systemic vasculitis that involves multiple organ systems and that can involve the kidney and spermatic cord. When the spermatic cord is involved, typically there is bilateral painful scrotal swelling with purpuric lesions involving the scrotum. Scrotal sonography should show normal testicular blood flow. Treatment is directed toward systemic treatment of the Henoch-Schönlein purpura. Isolated testicular vasculitis is less common than that in Henoch-Schönlein purpura; polyarteritis nodosa should be suspected.

VARICOCELE

A varicocele is a congenital condition in which there is abnormal dilation of the pampiniform plexus in the scrotum, often described as a "bag of worms" (Fig. 545-6). Dilation of the pampiniform venous plexus results from valvular incompetence of the internal spermatic vein. Approximately 15% of adult men have a varicocele; of these, approximately 10-15% are subfertile. Varicocele is the most common (and virtually the only) surgically correctable cause of subfertility in men. A varicocele is found in 5-15% of adolescent boys, but it rarely is diagnosed in boys younger than 10 yr old, because the varicocele becomes distended only after the increased blood flow associated with puberty occurs. Varicoceles occur predominantly on the left side, are bilateral in 2% of cases, and rarely involve the right side only. A varicocele in a boy younger than age 10 yr or on the right side might indicate an abdominal or retroperitoneal mass; an abdominal sonogram or CT scan should be performed in such cases.

A varicocele typically is a painless paratesticular mass. Occasionally patients describe a dull ache in the affected testis. Usually the varicocele is not apparent when the patient is supine because it is decompressed; in contrast, the varicocele becomes prominent when the patient is

Figure 545-6 Left varicocele in an adolescent boy.

Figure 545-7 Newborn with large right hydrocele.

standing and enlarges with a Valsalva maneuver. Many pediatricians do not routinely screen adolescents for a varicocele. Varicoceles typically are graded from 1-3 with the boy standing: **grade 1** is palpable only with Valsalva; **grade 2** is palpable without Valsalva but is not visible on inspection; and **grade 3** is visible with inspection. Boys with a grade 3 varicocele are at greatest risk for testicular growth arrest. Testicular size should be documented with calipers, an orchidometer, or scrotal sonography, because if the affected left testis is significantly smaller than the right testis, spermatogenesis probably has been adversely affected. A semen analysis should be considered in sexually mature adolescents who are Tanner stage V.

The goal of varicocelectomy is to maximize chances for fertility. Surgical treatment of varicoceles is indicated in boys with a significant disparity in testicular size or pain in the affected testis or if the contralateral testis is diseased or absent. Typically the involved testis enlarges and catches up with the normal testis over the following 1-2 yr. Varicocelectomy should also be considered in boys with a large grade 3 varicocele, even if there is not a disparity in testicular size. Surgical repair is accomplished with a variety of techniques by ligation of the veins of the pampiniform plexus laparoscopically or through an inguinal or subinguinal incision (with or without an operating microscope) or by ligating the internal spermatic vein in the retroperitoneum. The operation is performed on an ambulatory basis.

SPERMATOCELE

A spermatocele is a cystic lesion that contains sperm and is attached to the upper pole of the sexually mature testis. Spermatoceles usually are painless and are incidental findings on physical examination. Enlargement of the spermatocele or significant pain is an indication for removal.

HYDROCELE

Etiology

A hydrocele is an accumulation of fluid in the tunica vaginalis (Fig. 545-7). Between 1% and 2% of neonates have a hydrocele. In most cases, the hydrocele is noncommunicating (the processus vaginalis was obliterated during development). In such cases, the hydrocele fluid disappears by 1 yr of age. If there is a persistently patent processus, the hydrocele persists and becomes progressively larger during the day and is small in the morning. A rare variant of a hydrocele is the abdominoscrotal hydrocele, in which there is a large, tense hydrocele that extends into the lower abdominal cavity. In some older boys, a noncommunicating hydrocele can result from an inflammatory condition within the scrotum, such as testicular torsion, torsion of the appendix testis, epididymitis, or testicular tumor. The long-term risk of a communicating hydrocele is the development of an inguinal hernia. Some older boys and adolescents also develop a hydrocele. In some cases hydrocele develop acutely after an episode of scrotal trauma or epididymoorchitis, whereas others develop more insidiously.

Diagnosis

On examination, hydroceles are smooth and nontender. Transillumination of the scrotum confirms the fluid-filled nature of the mass. It is important to palpate the testis, because some young men develop a hydrocele in association with a testis tumor. If compression of the fluid-filled mass completely reduces the hydrocele, an inguinal hernia/hydrocele is the likely diagnosis.

Treatment

Most congenital hydroceles resolve by 12 mo of age following reabsorption of the hydrocele fluid. If the hydrocele is large and tense, however, early surgical correction should be considered, because it is difficult to verify that the child does not have a hernia, and large hydroceles rarely disappear spontaneously. Hydroceles persisting beyond 12-18 mo usually are communicating and should be repaired. Surgical correction is similar to a herniorrhaphy (see Chapter 346). Through an inguinal incision, the spermatic cord is identified, the hydrocele fluid is drained, and a high ligation of the processus vaginalis is performed. If an older boy has a large hydrocele, often diagnostic laparoscopy can be performed to determine whether there is a patent processus vaginalis, and if the internal ring is closed, then the hydrocele may be corrected with a scrotal incision.

INGUINAL HERNIA

Inguinal hernia is discussed in Chapter 346.

TESTICULAR TUMOR

Testicular and paratesticular tumors can occur at any age, even in the newborn. Approximately 35% of prepubertal testis tumors are malignant; most commonly they are yolk sac tumors, although rhabdomyosarcoma and leukemia also can occur in this age group. In adolescents, 98% of painless solid testicular masses are malignant (see Chapter 503). Most manifest as a painless, hard testicular mass that does not transilluminate. Scrotal ultrasonography should be performed to confirm the finding of a testicular mass and it can help to delineate the type of testis tumor. Serum tumor markers, including **α-fetoprotein** and **β-human**

chorionic gonadotropin, should be drawn. Definitive therapy includes surgical exploration through an inguinal incision. In most cases, a radical orchiectomy, consisting of removal of the entire testis and spermatic cord, is performed. In a prepubertal boy, if the ultrasonographic study or surgical exploration suggests that the tumor is localized and benign, such as a teratoma or epidermoid cyst, testis-sparing surgery with removal only of the mass may be appropriate.

Testicular microlithiasis identified incidentally with ultrasonography may be a risk factor for future neoplasia.

Chapter 546

Trauma to the Genitourinary Tract

Jack S. Elder

ETIOLOGY

Most injuries to the genitourinary tract in children result from blunt trauma during falls, athletic activities, or motor vehicle crashes (see Chapter 72). Children are at greater risk of blunt renal injury than are adults, because they have less body fat and because the kidneys are not located directly behind the ribs. Children with a preexisting renal anomaly, such as hydronephrosis secondary to a ureteropelvic junction obstruction, horseshoe kidney, or renal ectopia, also are at increased risk for renal injury. Blunt abdominal or flank trauma often causes a renal injury. Falling can cause a deceleration injury that results in an injury to the renal pedicle, interrupting blood flow to the kidney. If the bladder is full, blunt lower abdominal trauma can cause a bladder rupture. Rupture of the membranous urethra occurs in 5% of pelvic fractures. Straddle injuries usually are associated with trauma to the bulbous urethra.

Symptoms and signs of urinary tract injury include gross or microscopic hematuria, bleeding from the urethral meatus, abdominal or flank pain, a flank mass, fractured lower ribs or lumbar transverse processes, and a perineal or scrotal hematoma.

In more than 50% of cases there also are major injuries to the brain, spinal cord, skeleton, lungs, or abdominal organs.

DIAGNOSIS

Evaluation of the patient begins after an adequate airway has been established and the patient is hemodynamically stable (see Chapter 67). With significant abdominal injury, gross hematuria or >50 red blood cells per high-power field, or suspicion of renal injury (deceleration injury, flank pain or bruise), renal imaging is indicated. The bladder should be catheterized unless blood is dripping from the urethral meatus, which is an indication of potential urethral injury. Passing the catheter in the presence of a urethral injury can increase the extent of the damage and convert a partial membranous urethral tear into a total disruption. In these patients, a retrograde urethrogram should be performed by injecting radiopaque contrast medium into the urethral meatus under fluoroscopy. Oblique radiographs demonstrate the extent of the injury and whether urethral continuity is preserved or has been disrupted.

A **3-phase spiral CT scan** should be performed to evaluate the kidneys, ureters, and bladder. The delayed images are important to detect renal extravasation of blood or urine. Prompt function of both kidneys without extravasation usually excludes significant renal injury. Renal injuries are classified according to the grading scale presented in Table 546-1. Minor renal injuries are most common; these include contusion of the renal parenchyma and shallow cortical lacerations not involving the collecting system. Major renal injuries include deep lacerations involving the collecting system, the shattered kidney, and renal pedicle injuries (Fig. 546-1). Complete absence of function of 1 kidney without contralateral compensatory hypertrophy (indicating congenital absence) should be regarded as an indication of major injury to the renal pedicle. Renal angiography, once used for further evaluation of renal injuries, particularly if a renal pedicle injury is suspected, now is rarely used because such patients are often hemodynamically unstable, and management is not significantly affected by the findings. In some cases, a preexisting renal anomaly is demonstrated on the study. A ruptured ureteropelvic junction obstruction may be apparent if the kidney is intact but the distal ureter is not visualized.

If there is a pelvic fracture, a urethral transection injury should be suspected. The risk is directly related to the number of broken pubic

Table 546-1 Grading of Renal Injuries

GRADE	DESCRIPTION
1	Renal contusion or subcapsular hematoma
2	Nonexpanding perirenal hematoma, <1 cm parenchymal laceration, no urinary extravasation; all renal fragments viable; confined to renal retroperitoneum
3	Nonexpanding perirenal hematoma, >1 cm parenchymal laceration, no urinary extravasation; renal fragments may be viable or devitalized
4	Laceration extending into the collecting system with urinary extravasation; renal fragments may be vital or devitalized *or* Injury to the main renal vasculature with contained hemorrhage
5	Completely shattered kidney; by definition multiple major lacerations >1 cm associated with multiple devitalized fragments *or* Injury to the main renal vasculature with uncontrolled hemorrhage, renal hilar avulsion

Figure 546-1 CT scan of a girl who sustained major renal injury when she fell off a bicycle. The scan demonstrates a ruptured right kidney with urinary extravasation.

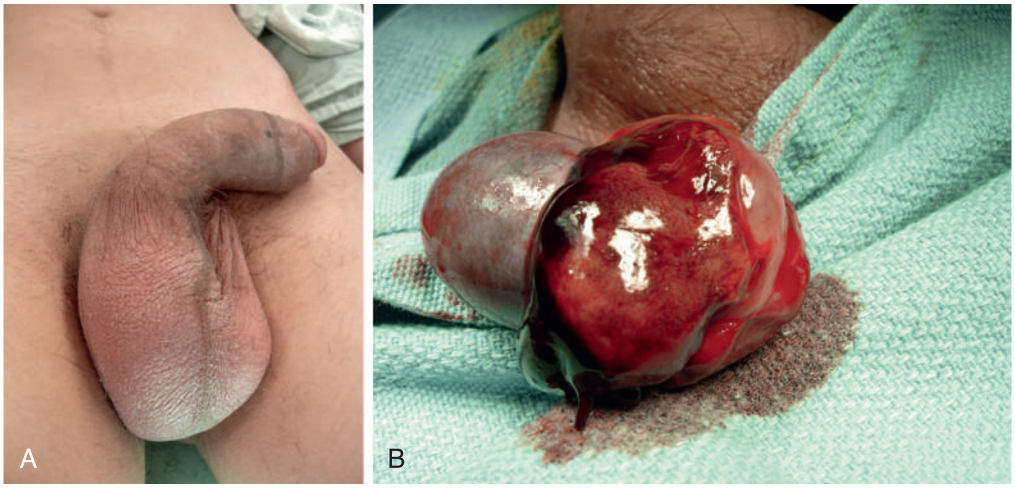

Figure 546-2 **A,** Adolescent boy with blunt right testicular injury. **B,** Tunica albuginea of testis is ruptured; the patient underwent debridement and closure of testicular capsule.

rami and whether there is separation of the pubic symphysis or displacement of the posterior pubic arch. Radiographic evaluation with retrograde urethrography should be performed if there is blood at the urethral or vaginal meatus, inability to void, and a perineal or penile hematoma.

TREATMENT

Minor renal injuries such as contusions are managed by bed rest and monitoring of vital signs until abdominal or flank discomfort and gross hematuria have resolved. Children with a major renal injury usually are admitted to an intensive care unit for continuous monitoring of vital signs and urine output. Intravenous antibiotics are also administered. These injuries also are managed nonoperatively, because Gerota's fascia often causes tamponade of bleeding from the kidney, and dramatic healing of the injured parenchyma can occur even with significant urinary extravasation.

Approximately 10% of children with a major renal injury undergo surgical exploration because of hemodynamic instability, persistent extravasation, or persistent hematuria or to correct a congenital renal deformity. It can be difficult to identify normal and devitalized parenchyma, and the likelihood of having to remove the kidney is significant. If the child is undergoing exploration for other abdominal injuries, the injured kidney is examined. If there is persistent extravasation because of intermittent ureteral obstruction from a blood clot, passage of a temporary double-J stent endoscopically between the bladder and kidney might allow resolution. If the renal pedicle is injured, nephrectomy is necessary. The kidney can be salvaged by emergency renal revascularization only if the kidney is explored within 2-3 hr of the injury. Virtually all penetrating injuries of the kidneys should be explored.

In addition to loss of renal function, the main long-term complication of renal injury is renin-mediated hypertension. Children who sustain significant renal injuries should have periodic measurement of blood pressure if they have any residual renal abnormality.

Ureteral injuries usually are iatrogenic. Injuries of the ureter by blunt or penetrating trauma require immediate surgical attention.

When the bladder can be catheterized, a static cystogram is obtained, infusing a contrast solution through the catheter by gravity, ideally using fluoroscopy. Flat and oblique views are often obtained; a postvoid film also should be obtained because, in some cases, extravasation may be hidden by the full bladder.

Bladder ruptures can be intraperitoneal or extraperitoneal. All intraperitoneal ruptures require surgical repair. Minor extraperitoneal near-ruptures might be treated by catheter drainage but generally require surgical treatment.

Treatment of a membranous urethral injury is controversial. Erectile dysfunction, urethral stricture, and urinary incontinence are the major late complications of rupture of the membranous urethra, and therapy is directed at minimizing the risk of these problems. A large pelvic hematoma with tamponade often is present, and an immediate attempt to repair the injury can be technically difficult and result in significant hemorrhage. Many such injuries are managed initially by temporary suprapubic cystostomy, with continuous bladder drainage for 3-6 mo. Subsequently, open or endoscopic urethroplasty can be performed. Alternatively, some try to achieve urethral continuity under anesthesia and leave a urethral catheter for several months. These patients typically require subsequent open urethroplasty.

Penile injury is uncommon. A risk of newborn circumcision with a Mogen clamp is partial or complete glans amputation. With immediate surgical repair, often the excised glans tissue can be replaced as a free graft. Some boys who are in the process of toilet training sustain an injury to the glans penis if the lid of the toilet falls while they are urinating. These boys often have a hematoma covering the distal half of the glans. Typically, they have no difficulty urinating and do not need extensive evaluation. Some male infants develop an inadvertent hair coil tourniquet or strangulation injury. Typically a very narrow constriction is noted with severe distal penile swelling and pain. Identification and incision of the hair allows prompt resolution of the edema. The urethra and penile vascularity should be assessed after release of the hair coil. Adolescent boys who indulge in extremely vigorous sexual intercourse may sustain rupture of one of the corporal bodies. These boys have severe swelling of the penile shaft and require emergency exploration and repair. Boys with penetrating injuries of the penis also require emergency debridement and repair.

Testicular injuries are relatively uncommon in children because of the small size of the testes and their mobility within the scrotum. Such injuries usually result from blunt trauma during athletic activity. Typically, these boys have significant scrotal swelling, testicular pain, and tenderness (Fig. 546-2*A*). Ultrasonography demonstrates rupture of the tunica albuginea, which is the capsule of the testis, and surrounding hemorrhage. Prompt surgical treatment of testicular injuries increases the salvage rate (Fig. 546-2*B*). An uncommon injury is the zipper injury, which can affect either the scrotum or foreskin. This problem generally occurs in boys who do not wear underwear. The zipper can be cut with bone cutters or metal cutters. Sedation generally is unnecessary.

Chapter 547

Urinary Lithiasis

Jack S. Elder

Urinary lithiasis in children is related to genetic, climatic, dietary, and socioeconomic factors. The incidence is increasing: in 1996 the rate of symptomatic nephrolithiasis was 7.9 in 10,000, whereas in 2007 it was 18.5 in 10,000. Adolescents are 10 times more likely to have a symptomatic calculus compared to children 0-3 yr. The increase in stone disease in the United States is attributed to obesity and changes in dietary habits, such as increased sodium and fructose intake, and decreased calcium and water intake.

Urolithiasis is less common in the United States than in other parts of the world. Approximately 7% of urinary calculi occur in children younger than 16 yr of age. In the United States, many children with stone disease have a metabolic abnormality. The exceptions are patients with a neuropathic bladder (see Chapter 542), who are prone to infection-initiated renal stones, and those who have urinary tract reconstruction with small or large intestine, which predisposes to bladder calculi. The incidence of metabolic stones is similar in boys and girls; they are most common in southeastern United States and are uncommon in African-Americans. In Southeast Asia, urinary calculi are endemic and are related to dietary factors. Contamination of infant formula with the organic base and illegally added nitrogen-containing food additive melamine was reported in China in 2008 and is the source of much study in that country.

STONE FORMATION

Nearly 90% of urinary stones contain calcium as a major constituent, and 60% are composed of calcium oxalate. Most "spontaneous" stones are composed of calcium, oxalate, or phosphate crystals; others are caused by uric acid, cystine, ammonium crystals, or phosphate crystals, or a combination of these substances (Table 547-1). The risk of stone formation increases in the presence of increasing concentrations of these crystals and is reduced with increasing concentrations of urinary inhibitors. Renal calculi develop from crystals that form on the calyx and aggregate to form a calculus. Bladder calculi may be stones that formed in the kidney and traveled down the ureter, or they can form primarily in the bladder.

Low urine volume, low urine pH, calcium, sodium, oxalate, and urate are known to promote stone formation. Many inorganic (e.g., citrate, magnesium) and organic (e.g., glycosaminoglycans, osteopontin) substances are known to inhibit stone formation. Organic inhibitory compounds adsorb to the surface of the crystal, thereby inhibiting crystal growth and nucleation.

Stone formation depends on 4 factors: matrix, precipitation–crystallization, epitaxy, and the absence of inhibitors of stone formation in the urine. **Matrix** is a mixture of protein, nonamino sugars, glucosamine, water, and organic ash that makes up 2-9% of the dry weight of urinary stones and is arranged within the stones in organized concentric laminations. **Precipitation–crystallization** refers to supersaturation of the urine with specific ions composing the crystal. Crystals aggregate by chemical and electrical forces. Increasing the saturation of urine with respect to the ions increases the rate of nucleation, crystal growth, and aggregation and increases the likelihood of stone formation and growth. **Epitaxy** refers to the aggregation of crystals of different composition but similar lattice structure, thus forming stones of a heterogeneous nature. The lattice structures of calcium oxalate and monosodium urate have similar structures, and calcium oxalate crystals can aggregate on a nucleus of monosodium urate crystals. Urine also contains **inhibitors of stone formation,** including citrate, diphosphonate, and magnesium ion.

Table 547-1 Classification of Urolithiasis
CALCIUM STONES (CALCIUM OXALATE AND CALCIUM PHOSPHATE)*
Hypercalciuria
Absorptive: increased Ca absorption from gut; types I and II
Renal leak: decreased tubular reabsorption of Ca
Resorptive
Primary hyperparathyroidism (rare in children)
Iatrogenic
Loop diuretics
Ketogenic diet
Corticosteroids
Adrenocorticotropic hormone administration
Methylxanthines (theophylline, aminophylline)
Distal renal tubular acidosis, type 1 (calcium phosphate)
Hypocitraturia—citrate most important inhibitor of Ca crystallization
Vitamin D excess
Immobilization
Sarcoidosis
Cushing disease
Hyperuricosuria
Heterozygous cystinuria
Hyperoxaluria (calcium oxalate)
Primary hyperoxaluria, types 1 and 2
Secondary hyperoxaluria
Enteric hyperoxaluria
CYSTINE STONES
Cystinuria
STRUVITE STONES (MAGNESIUM AMMONIUM PHOSPHATE)
Urinary tract infection (urea-splitting organism)
Foreign body
Urinary stasis
URIC ACID STONES
Hyperuricosuria
Lesch-Nyhan syndrome
Myeloproliferative disorders
After chemotherapy
Inflammatory bowel disease
INDINAVIR STONES
MELAMINE
NEPHROCALCINOSIS

*Most common.

CLINICAL MANIFESTATIONS

Children with urolithiasis usually have gross or microscopic hematuria. If the calculus causes obstruction, then severe flank pain (renal colic) or abdominal pain occurs. The calculus typically causes obstruction at areas of narrowing of the urinary tract—the ureteropelvic junction, where the ureter crosses the iliac vessels, and the ureterovesical junction. The ureter progressively narrows distally, and its most narrow segment is the ureterovesical junction. Typically the pain radiates anteriorly to the scrotum or labia. Often the pain is intermittent, corresponding to periods of obstruction of urine flow, which increases the pressure in the collecting system. If the calculus is in the distal ureter, the child can have irritative symptoms of dysuria, urgency, and frequency. If the stone passes into the bladder, the child usually is asymptomatic. If the stone is in the urethra, dysuria and difficulty voiding can result, particularly in boys. Some children pass small amounts of gravel-like material. Stones can also be asymptomatic, although it is uncommon to pass a ureteral calculus without symptoms.

DIAGNOSIS

Approximately 90% of urinary calculi are calcified to some degree and consequently are radiopaque on a plain abdominal film. However, many calculi are only a few millimeters in diameter and are difficult to

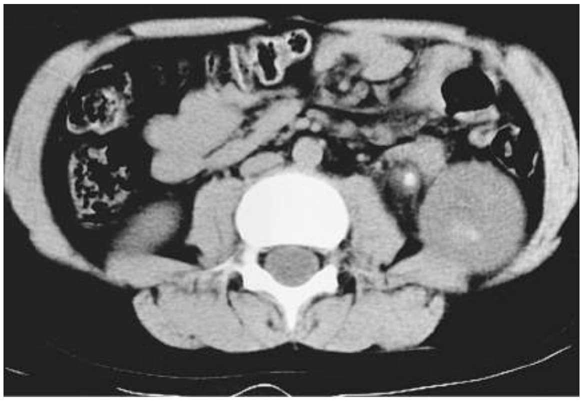

Figure 547-1 Noncontrast CT scan of the midabdomen in a male infant with cystinuria shows a left-sided calculus at the ureteropelvic junction with proximal hydronephrosis.

see, particularly if they are in the ureter. Struvite (magnesium ammonium phosphate) stones are radiopaque. Cystine, xanthine, and uric acid calculi may be radiolucent but often are slightly opacified. Some children have **nephrocalcinosis,** which is calcification of the renal tissue itself. Nephrocalcinosis is seen most commonly in premature neonates receiving furosemide, which causes hypercalciuria, and in children with medullary sponge kidney.

In a child with suspected renal colic, there are multiple imaging options. The most accurate study is an **unenhanced spiral CT scan** of the abdomen and pelvis (Fig. 547-1). This study takes only a few minutes to perform, has 96% sensitivity and specificity in delineating the number and location of calculi, and demonstrates whether the involved kidney is hydronephrotic. However, the radiation exposure is high. An alternative is to obtain a plain radiograph of the abdomen and pelvis plus a renal ultrasonogram. These studies can demonstrate hydronephrosis and possibly the calculus on the radiograph; however, the calculus is not visualized on sonography unless it is adjacent to the bladder. In addition, renal calculi <3 mm typically are not seen. Consequently, the clinician needs to carefully balance the risks of CT imaging against the lower sensitivity of the plain abdominal film plus sonography.

In 2008 the Society for Pediatric Radiology initiated the Image Gently initiative to educate providers on the risks of radiologic imaging in children and to encourage the use of limited imaging in children, particularly those with suspected urolithiasis (http://www.pedrad.org/associations/5364/ig/). In a child with an already-diagnosed calculus, serial plain x-rays or renal ultrasonography can be used to follow the status of the calculus, such as whether it has grown or diminished in size or has moved. If a child has a renal pelvic calculus, a ureteropelvic junction obstruction should be suspected. In some cases, it can be difficult to determine whether hydronephrosis in such a child is secondary to an obstructing stone, ureteropelvic junction obstruction, or both.

Any material that resembles a calculus should be sent for analysis by a laboratory that specializes in identifying the components of urinary calculi.

METABOLIC EVALUATION

A metabolic evaluation for the most common predisposing factors should be undertaken in all children with urolithiasis, bearing in mind that structural, infectious, and metabolic factors often coexist. This evaluation should not be undertaken in a child who is in the process of passing a stone, because the altered diet and hydration status, as well as the effect of obstruction on the kidney, can alter the results of the study. Table 547-2 lists the basic laboratory studies required, and Table 547-3 shows the normal values for 24-hr urine collections. In children with hypercalciuria, further studies of calcium excretion with dietary calcium restriction and calcium loading are necessary.

Table 547-2 Laboratory Tests Suggested for Evaluation of Urolithiasis

SERUM	URINE
Calcium	Urinalysis
Phosphorus	Urine culture
Uric acid	Calcium : creatinine ratio
Electrolytes and anion gap	Spot test for cystinuria
Creatinine	24 hr collection for:
Alkaline phosphatase	Creatinine clearance
	Calcium
	Phosphate
	Oxalate
	Uric acid
	Dibasic amino acids (if cystine spot test result is positive)

PATHOGENESIS OF SPECIFIC RENAL CALCULI

Calcium Oxalate and Calcium Phosphate Calculi

Most urinary calculi in children in the United States are composed of calcium oxalate and/or calcium phosphate. The most common metabolic abnormality in these patients is normocalcemic **hypercalciuria.** Between 30% and 60% of children with calcium stones have hypercalciuria without hypercalcemia. Other metabolic aberrations that predispose to stone disease include hyperoxaluria, hyperuricosuria, hypocitruria, heterozygous cystinuria, hypomagnesuria, hyperparathyroidism, and renal tubular acidosis (see Chapter 529).

Hypercalciuria may be absorptive, renal, or resorptive. The primary disturbance in absorptive hypercalciuria is intestinal hyperabsorption of calcium. In some children, an increase in 1,25-dihydroxyvitamin D is associated with the increased calcium absorption, whereas in others the process is independent of vitamin D. **Renal hypercalciuria** refers to impaired renal tubular reabsorption of calcium (see Chapter 519.8). Renal leak of calcium causes mild hypocalcemia, which triggers an increased production of parathyroid hormone, with increased intestinal absorption of calcium and increased mobilization of calcium stores. Resorptive hypercalciuria is uncommon and is found in patients with primary hyperparathyroidism. Excess parathyroid hormone secretion stimulates intestinal absorption of calcium and mobilization of calcium stores. Table 547-4 summarizes the metabolic evaluation of children with hypercalciuria.

Hyperoxaluria is another potentially important cause of calcium stones. Oxalate increases the solubility product of calcium oxalate crystallization 7-10 times more than calcium. Consequently, hyperoxaluria significantly increases the likelihood of calcium oxalate precipitation. Oxalate is found in high concentration in tea, coffee, spinach, and rhubarb. Primary hyperoxaluria is a rare autosomal recessive disorder that can be subclassified into glycolic aciduria and L-glyceric aciduria. Most patients with primary hyperoxaluria have glycolic aciduria; oxalic and glycolic acids are increased in the urine of affected persons. Both defects cause increased endogenous production of oxalate, with hyperoxaluria, urolithiasis, nephrocalcinosis, and injury to the kidneys. Death from renal failure occurs by age 20 yr in untreated patients. **Oxalosis,** defined as extrarenal deposition of calcium oxalate, occurs when renal insufficiency is present with elevated plasma oxalate. Calcium oxalate deposits appear first in blood vessels and bone marrow, and with time they appear throughout the body. Secondary hyperoxaluria is more common and can occur in patients with increased intake of oxalate and oxalate precursors such as vitamin C, in those with pyridoxine deficiency, and in children with intestinal malabsorption.

Enteric hyperoxaluria refers to disorders such as inflammatory bowel disease (see Chapter 336), pancreatic insufficiency (see Chapter 350), and biliary disease (see Chapter 356), in which there is gastrointestinal malabsorption of fatty acids, which bind intraluminal calcium and form salts that are excreted in the feces. Normally, calcium forms a complex with oxalate to reduce oxalate absorption, but if calcium is unavailable, there is increased absorption of unbound oxalate.

Table 547-3 Urine Chemistry: Normal Values

URINE CONSTITUENT	AGE	RANDOM	TIMED	COMMENTS
Calcium	0-6 mo 7-12 mo ≥2 yr	<0.8 mg/mg creat <0.6 mg/mg creat <0.21 mg/mg creat	<4 mg/kg/24 hr	Prandial variation Sodium-dependent
Oxalate*	<1 yr 1-<5 yr 5-12 yr >12 yr	0.15-0.26 mmol/mmol creat 0.11-0.12 mmol/mmol creat 0.006-0.15 mmol/mmol creat 0.002-0.083 mmol/mmol creat	≥2 yr: <0.5 mmol/1.73 m^2/24 hr	Random urine mmol/mmol highly age-dependent Excretion rate/1.73 m^2 constant through childhood and adulthood
Uric acid	Term infant >3 yr	3.3 mg/dL GFR† <0.53 mg/dL GFR	<815 mg/1.73 m^2/24 hr	Excretion rate/1.73 m^2 from >1 yr age; constant through childhood
Magnesium	>2 yr	<0.12 mg/mg creat	<88 mg/1.73 m^2/24 hr	Excretion rate/1.73 m^2 constant through childhood
Citrate		>400 mg/g creat		Limited data available for children
Cystine		<75 mg/g creat	<60 mg/1.73 m2/24 hr	Cystine >250 mg/g creat suggests homozygous cystinuria

*Oxalate oxidase assay.
†(mg/dL uric acid) (serum creatinine concentration/urine creatinine concentration).
creat, Creatinine; GFR, glomerular filtration rate.

Table 547-4 Metabolic Evaluation of Children with Hypercalciuria

TYPE	SERUM CALCIUM	RESTRICTED CALCIUM (URINE)	FASTING CALCIUM (URINE)	CALCIUM LOAD (URINE)	PARATHYROID HORMONE (SERUM)
Absorptive	N	N or I	N	I	I
Renal	N	I	I	I	N
Resorptive	I	I	I	I	I

I, increased; N, normal.

Hypocitraturia refers to a low excretion of citrate, which is an important inhibitor of calcium stone formation. Citrate acts as an inhibitor of calcium urolithiasis by forming complexes with calcium, increasing the solubility of calcium in the urine, and inhibiting the aggregation of calcium phosphate and calcium oxalate crystals. Disorders such as chronic diarrhea, intestinal malabsorption, and renal tubular acidosis (see below) can cause hypocitraturia. It may also be idiopathic.

Renal tubular acidosis (RTA) is a syndrome involving a disturbance of acid–base balance within the kidney that can be classified into 3 types, one of which predisposes to renal calculi that typically are calcium phosphate (see Chapter 529). In type 1 RTA, the distal nephron does not secrete hydrogen ion into the distal tubule. The urine pH is never <5.8, and hyperchloremic hypokalemic acidosis results. Patients acquire nephrolithiasis, nephrocalcinosis, muscle weakness, and osteomalacia. Type 1 RTA can be an autosomal dominant disorder, but more often it is acquired and associated with systemic diseases such as Sjögren syndrome, Wilson disease, primary biliary cirrhosis, and lymphocytic thyroiditis, or it results from amphotericin B, lithium, or toluene (an organic solvent associated with glue sniffing).

From 5-8% of patients with **cystic fibrosis** (see Chapter 403) have urolithiasis. Typically the stones are calcium, and they often become manifest in adolescence or young adulthood. Microscopic nephrocalcinosis also occurs in younger children with the disease. These patients do not have hypercalciuria, and the propensity for urolithiasis has been speculated to result from an inability to excrete a sodium chloride load or from intestinal malabsorption.

Other disorders can play a role in causing calcium stones. **Hyperuricosuria** may be related to the epitactic growth of calcium oxalate crystals around a nucleus of uric acid crystals or to the action of uric acid as a counter inhibitor of urinary mucopolysaccharides, which inhibit calcium oxalate crystallization. **Heterozygous cystinuria** is found in some patients with calcium stones. The mechanism is unknown but may be similar to that of uric acid. Sarcoidosis (see Chapter 165) causes an increased sensitivity to vitamin D_3 and thus an increased absorption of calcium from the gastrointestinal tract. In Lesch-Nyhan syndrome (see Chapter 89), there is excessive uric acid synthesis. These patients are more likely to form uric acid stones, but some of these stones may be calcified. **Immobility** can cause hypercalciuria by mobilization of calcium stores. High-dose corticosteroids can cause hypercalciuria and calcium oxalate precipitation. Furosemide, which is administered in the neonatal intensive care unit, also can cause severe hypercalciuria, urolithiasis, and nephrocalcinosis.

In some children, calcium calculi are idiopathic. A complete metabolic evaluation must be performed before this diagnosis is made.

Cystine Calculi

Cystinuria accounts for 1% of renal calculi in children. The condition is a rare autosomal recessive disorder of the epithelial cells of the renal tubule that prevents absorption of the 4 dibasic amino acids (cystine, ornithine, arginine, lysine) and results in excessive urinary excretion of these products. The only known complication of this familial disease is the formation of calculi, because of the low solubility of cystine. The patients usually have acidic urine, which leads to a higher rate of

precipitation. In the homozygous patient, the daily excretion of cystine usually exceeds 500 mg, and stone formation occurs at an early age. Heterozygotes excrete 100-300 mg/day and typically do not have clinical urolithiasis. The sulfur content of cystine gives these stones their faint radiopaque appearance.

Struvite Calculi

Urinary tract infections (see Chapter 538) caused by urea-splitting organisms (most often *Proteus* spp., and occasionally *Klebsiella* spp., *Escherichia coli, Pseudomonas* spp., and others) result in urinary alkalinization and excessive production of ammonia, which can lead to the precipitation of magnesium ammonium phosphate (struvite) and calcium phosphate. In the kidney, the calculi often have a staghorn configuration, filling the calyces. The calculi act as foreign bodies, causing obstruction, perpetuating infection, and causing gradual kidney damage. Patients with struvite stones also can have metabolic abnormalities that predispose to stone formation. These stones often are seen in children with neuropathic bladder, particularly those who have undergone a urinary tract reconstructive procedure (see Chapter 542). Struvite stones also can form in the reconstructed bladder of children who have undergone augmentation cystoplasty or continent urinary diversion.

Uric Acid Calculi

Calculi containing uric acid represent <5% of all cases of lithiasis in children in the United States but are more common in less-developed areas of the world. Hyperuricosuria with or without hyperuricemia is the common underlying factor in most cases. The stones are radiolucent on x-ray. The diagnosis should be suspected in a patient with persistently acid urine and urate crystalluria.

Hyperuricosuria can result from various inborn errors of purine metabolism that lead to overproduction of uric acid, the end product of purine metabolism in humans. Children with the Lesch-Nyhan syndrome and patients with glucose-6-phosphatase deficiency (see Chapter 87) form urate calculi as well. In children with short-bowel syndrome (see Chapter 338.7), and particularly those with ileostomies, chronic dehydration and acidosis sometimes are complicated by uric acid lithiasis.

One of the most common causes of uric acid lithiasis is the rapid turnover of purine with some tumors and myeloproliferative diseases. The risk of uric acid lithiasis is especially great when treatment of these diseases causes rapid breakdown of nucleoproteins. Uric acid calculi or “sludge” can fill the entire upper collecting system and cause renal failure and even anuria. Urates also are present within calcium-containing stones. In these cases, >1 predisposing factor for stone formation can exist.

Indinavir Calculi

Indinavir sulfate is a protease inhibitor approved for treating HIV infection (see Chapter 276). Up to 4% of patients acquire symptomatic nephrolithiasis. Most of the calculi are radiolucent and are composed of indinavir-based monohydrate, although calcium oxalate and/or phosphate have been present in some. After each dose, 12% of the drug is excreted unchanged in the urine. The urine in these patients often contains crystals of characteristic rectangles and fan-shaped or starburst crystals. Indinavir is soluble at a pH of <5.5. Consequently, dissolution therapy by urinary acidification with ammonium chloride or ascorbic acid should be considered.

Nephrocalcinosis

Nephrocalcinosis refers to calcium deposition within the renal tissue. Often nephrocalcinosis is associated with urolithiasis. The most common causes are furosemide (administered to premature neonates), distal RTA, hyperparathyroidism, medullary sponge kidney, hypophosphatemic rickets, sarcoidosis, cortical necrosis, hyperoxaluria, prolonged immobilization, Cushing syndrome, hyperuricosuria, monogenetic causes of hypertension, and renal candidiasis.

TREATMENT

In a child with a renal or ureteral calculus, the decision whether to remove the stone depends on its location, size, and composition (if known) and whether obstruction and/or infection is present. Pain is managed with nonsteroidal antiinflammatory drugs or opiates. Small ureteral calculi often pass spontaneously, although the child might experience severe renal colic. The narrowest segment of the ureter is the ureterovesical junction. **α-Adrenergic blockers,** such as tamsulosin, terazosin, and doxazosin, facilitate stone passage in children and adults by decreasing ureteral pressure below the stone and decreasing the frequency of the peristaltic contractions of the obstructed ureter. In many cases, passage of a **ureteral stent** past the stone endoscopically relieves pain and dilates the ureter sufficiently to allow the calculus to pass. In cases such as children with a uric acid calculus or an infant with a furosemide-associated calculus, dissolution alkaline therapy may be effective.

If the calculus does not pass or seems unlikely to pass or if there is associated urinary tract infection, removal is necessary (Table 547-5). **Lithotripsy** of bladder, ureteral, and small renal pelvic calculi using the holmium laser through a flexible or rigid ureteroscope is quite effective. Extracorporeal shock wave lithotripsy has been successfully applied to children with renal and ureteral stones, with a success rate of >75%. Another alternative is percutaneous nephrostolithotomy, in which access to the renal collecting system is obtained percutaneously, and the calculi are broken down by ultrasonic lithotripsy. In cases in which these modalities are unsuccessful, an alternative is laparoscopic removal; this procedure can be performed using the da Vinci robot.

In children with urolithiasis, the underlying metabolic disorder should be addressed (Table 547-6). Because lithiasis results from elevated concentrations of specific substances in the urine, maintaining a continuous high urine output by maintaining a high fluid intake often is an effective method of preventing further stones. The high fluid intake should be continued at night, and usually it is necessary for the child to get up at least once at night to urinate and drink more water.

Table 547-5 Primary Surgical Treatment Options vs Stone Size and Location

STONES	SHOCK WAVE LITHOTRIPSY	URETEROSCOPY	PERCUTANEOUS NEPHROLITHOTOMY
RENAL			
<1 cm	Most common	Optional	Optional
1-2 cm	Most common	Optional	Optional
>2 cm	Optional	Rare	Most common

A daily fluid intake of 2-2.5 L in adolescent stone formers is recommended, with greater intake during summer months.

Dietary sodium intake in children has increased significantly, up to 6.8 g/day as a consequence of increased consumption of salty, processed foods. High sodium intake increases urinary excretion of calcium and may result in hypocitraturia. In addition, increased salt intake induces metabolic acidosis. To compensate for the acid load, the kidneys conserve anions, including urinary citrate, which contributes to hypocitraturia. Reduction in dietary intake of sodium and increased potassium intake is indicated.

Although counterintuitive, low-calcium diets are less effective in the treatment of calcium stones than diets containing normal amounts of calcium and limited amounts of sodium and animal protein. Low-sodium, low-protein diets reduce urinary calcium and oxalate excretion. Children with stone disease should avoid excess calcium intake. However, children require calcium for bone development and recommendations for daily calcium intake vary by age. Consequently, calcium restriction in children should be avoided. Thiazide diuretics also reduce renal calcium excretion. Addition of potassium citrate, an inhibitor of calcium stones, with a dosage of 1-2 mEq/kg/24 hr is beneficial. An excellent source of citrate is lemonade, because 4 oz of lemon juice contains 84 mEq of citric acid. A daily mixture of 4 oz of reconstituted lemon juice in 2 L of water and sweetened to taste should significantly increase the urinary citrate level. In difficult cases, neutral orthophosphate should be given also, although it is poorly tolerated.

In patients with uric acid stones, allopurinol is effective. Allopurinol is an inhibitor of xanthine oxidase and is effective in reducing the production of both uric acid and 2,8-dihydroxyadenine and can help control recurrence of both types of stones. In addition, urinary alkalinization with sodium bicarbonate or sodium citrate is beneficial. The urine pH should be ≥6.5 and can be monitored at home by the family.

Maintaining a high urine pH can also prevent recurrence of cystine calculi. Cystine is much more soluble when the urinary pH is >7.5, and alkalinization of urine with sodium bicarbonate or sodium citrate is effective. Another important medication is D-penicillamine, which is a chelating agent that binds to cysteine or homocysteine, increasing the solubility of the product. Although poorly tolerated by many patients, it has been reported to be effective in dissolving cystine stones and in preventing recurrences when hydration and urinary alkalinization fail. *N*-Acetylcysteine appears to have low toxicity and may be effective in controlling cystinuria, but long-term experience with it is lacking.

Treatment of type 1 RTA involves correcting the metabolic acidosis and replacing lost potassium and sodium. Sodium or potassium citrate therapy, or both, is necessary. When the metabolic acidosis is corrected, the urinary citrate excretion returns to normal.

Treatment of primary hyperoxaluria involves liver transplantation because the defective enzymes are hepatic. Ideally, this procedure is performed before renal failure occurs. In the most severe cases, kidney transplantation is also necessary.

Gynecologic Problems of Childhood

PART XXV

Chapter 548

History and Physical Examination

Kathryn C. Stambough and Diane F. Merritt

HISTORY

The approach to both the history and physical examination of a child is often a collaborative effort that involves the child, her caregiver, and the provider. With a preverbal or very young patient, clinicians obtain the majority of the history from a parent or caregiver. Even for the very young patient, developmentally appropriate social questions directed to the patient can put her at ease and help to develop cooperation and rapport that will facilitate a subsequent examination. Specific patient, caregiver, or provider concerns about vaginal discharge or bleeding, pruritus, external genital lesions or abnormalities should direct a problem-focused history. In a patient presenting with vaginal bleeding, questions should focus on recent growth and development, signs of pubertal progression, trauma, vaginal discharge, medication exposure, and any history of foreign objects in the vagina. For complaints of vulvovaginal irritation, pruritus, or discharge, questions should concentrate on perineal hygiene, the onset and duration of symptoms, the presence and quality of discharge, exposure to skin irritants, recent antibiotic use, travel, presence of medical comorbidities or infections in the patient and her family members, and other systemic symptoms of illness or skin conditions. Throughout the history, the patient should be encouraged to ask her own questions. Occasionally, the child is brought to the clinician because she or her parents have concerns about anatomic findings, developmental changes, or congenital anomalies. It helps to understand the family's concerns and if a specific reason, event, or family history raised the need for a gynecologic consultation.

GYNECOLOGIC EXAMINATION

The physical examination of the patient should be tailored to the child's age, complaint, and any other concerns elicited in the history. The menstrual period should be included with an assessment of other vital signs as age appropriate.

Neonates

The delivering obstetrician should briefly examine the external genitals of female infants to confirm the patency of the vagina and assess the presence of any obvious genital anomalies. The pediatrician's newborn examination should note any abnormal findings such as ambiguous genitalia, imperforate hymen, urogenital abnormalities, abdominal mass, or inguinal hernia that might herald a gynecologic problem.

Placing the infant in the supine position with thighs flexed against the abdomen allows visualization of the neonate's external genitals. Estrogenic effects commonly notable in neonates include prominence of the labia majora and a white vaginal discharge. The labia minora and hymen may protrude slightly from the vestibule. A small amount of neonatal vaginal bleeding from endometrial sloughing following maternal hormone withdrawal might occur. Bleeding that is excessive or persistent beyond 1 mo of life requires further evaluation. Breast buds may be palpable at the time of the neonatal examination but should regress in the 1st mo of life; occasionally, nipple discharge occurs.

The vaginal orifice may be difficult to see. Gentle lateral traction on the labia majora usually allows complete visualization of the hymen and vaginal orifice. The hymen should be evaluated for patency. Most hymenal variations—imperforate, microperforate, septate—do not require treatment during the neonatal period. Variations should be noted and readdressed in subsequent visits. The hymen originates from the urogenital sinus. The uterus and vagina originate from the müllerian ducts. The concomitant renal malformations seen with müllerian anomalies are not associated with hymenal anomalies. Hymenal polyps seen in newborns typically regress in size as the maternal estrogen effects subside. Cervicovaginal mucus secretions can accumulate behind the blocked outflow tract of an imperforate hymen and manifest as a mucocolpos. *In this instance, correction of the imperforate hymen in the neonatal period is indicated if urinary obstruction occurs.*

The clitoris may appear large in proportion to the other genital structures, especially in premature infants. If the clitoris appears enlarged, the clitoral width should be measured; values >6 mm in a newborn indicate a need for further evaluation. *If clitoromegaly and ambiguous genitals are present, the obstetrician and pediatrician should immediately obtain expert consultation for evaluation of the infant and to counsel the parents.* Congenital adrenal hyperplasia is the most common cause of ambiguous genitals (accounting for more than 90% of cases), and the salt-wasting forms can lead to rapid dehydration with subsequent fluid and electrolyte imbalance (see Chapter 576). Delay in the diagnosis and treatment of congenital adrenal hyperplasia may be life-threatening.

In the neonate, the ovaries are <1 cm in diameter and average 1 cm^3 in volume. Antenatal or postnatal abdominopelvic ultrasound might reveal small simple ovarian cysts, which represent normal follicles. Because of the abdominal location of ovaries in the neonate, ovarian enlargement can manifest as a palpable abdominal mass. Large cysts (>4-5 cm) or those of a complex nature pose the risk of ovarian torsion, hemorrhage into the cyst, or, uncommonly, an ovarian tumor. A nonresolving or enlarging neonatal ovarian cyst warrants expert consultation. If the mass causes respiratory compromise or gastrointestinal obstruction, decompression is usually performed. Cyst aspiration can give temporary relief, but it is not recommended as the fluid aspirated is not reliable for diagnosis and fluid may reaccumulate. If a cystectomy is done for appropriate clinical indications the cyst wall should be surgically excised to prevent reaccumulation of fluid and to provide a pathologic diagnosis, the remaining ovarian tissue should be left in situ, and the contralateral ovary should be inspected. Preservation of normal ovarian tissue is recommended for all benign lesions, and salpingo-oophorectomy should not be performed unless clinically indicated.

Infants and Prepubertal Girls

As the maternal estrogen effect subsides, the genitals of the female infant change in appearance. The labia begin to flatten. The hymenal membrane loses its redundancy and becomes translucent. The hypoestrogenic prepubertal vaginal epithelium appears thin, red, and sensitive to the touch. The vaginal mucosa of young children can have longitudinal ridges running along the axis of the vagina at 3 o'clock, 6 o'clock, and 9 o'clock, which can cause small protrusions on the hymen at these locations. The cervix usually appears flat and flush with the vaginal vault. During infancy, the uterus regresses in size and does not return to its birth size until the 5th or 6th year. The prepubertal cervix : fundus ratio is 2 : 1.

As puberty approaches, the child experiences increasing endocrine activity of the hypothalamus, pituitary gland, adrenal gland, and ovaries (see Chapter 561). The labia majora begin to fill out, and the labia minora thicken and elongate as a result of increased estrogen levels. The hymen thickens and becomes more redundant. Clear or white physiologic secretions may be present. Breast buds begin to appear, either bilateral or initially unilateral with subsequent development of the contralateral breast.

Indications for Genital Examination

Genitourinary complaints or suspected genitourinary pathology warrant assessment of the external and internal genitals of pediatric patients, specifically in cases of vaginal bleeding, vaginal discharge, vulvar trauma, presence of a foreign body, perineal or pelvic masses, vulvovaginal ulcerative or inflammatory lesions, congenital anomalies, or suspected sexual abuse.

Preparation

The genital examination in prepubertal girls requires a gentle, patient approach to maximize cooperation and minimize fear and embarrassment. A clear, simple explanation of what the exam involves can facilitate the child's comfort and cooperation. The presence of a parent or caregiver during the entire examination provides reassurance for most children. For the older prepubertal patient, the physician may discuss whether the patient wishes to have a family member present during the examination. Even in the presence of the caregiver, the examiner should speak directly to the child. Prior to initiating any part of the examination, the provider should explicitly verify with both the patient and her caregiver that the caregiver has given permission for the examination. This provides an opportunity to explain to the child the privacy of body parts and who may examine or touch those areas. It is useful to educate the patient and caregiver about the basic anatomy and hygiene of the external genital area. Before each step of the examination, the physician should explain what will occur. Allowing an older child the option of watching her examination with a handheld mirror may contribute to her comfort and understanding. Forcible restraint is never indicated; if optimal evaluation is not possible, the clinician must assess the acuity of the complaint and pathology and determine the potential need for a multi-visit examination or an examination under anesthesia.

Positioning

A variety of techniques and positions can facilitate the genital examination in prepubertal patients. Children younger than 4 yr of age can be placed on the parent or caregiver's lap with the child's legs straddling the parent's thighs. If the child permits, she may be positioned on the table in the supine position with the hips fully abducted and the feet together in the frogleg (diamond or butterfly) position. Older children may prefer to use the stirrups. The head of the examination table should be raised so that eye contact can be maintained with the patient throughout the examination. When the child is supine, grasping the labia majora along the inferior portion between the thumb and index finger and gently pulling outward and posteriorly (labial traction) allows visualization of the vaginal introitus. Alternatively, the child may be placed in the knee–chest position with elevation of the buttocks and hips. This position provides exposure of the inferior portion of the hymen, the lower vagina, and possibly the upper vagina and cervix but has the disadvantage of having the child face away from the examiner.

Some extremely cooperative children tolerate a vaginoscopic examination in an outpatient office setting for better intravaginal assessment. The endoscope (either a cystoscope or a hysteroscope) is placed in the vagina and the labia are gently opposed, allowing the vagina to distend with water. This technique permits visualization of the vagina and cervix, allowing for the evaluation of an injury, lesion, and anatomic variant or for the presence of a foreign body. Application of 2% lidocaine gel at the introitus makes the insertion easier and less irritating for the patient. If a more complete examination is indicated or if the child is too young, frightened or unable to cooperate, an examination under anesthesia is recommended.

Documentation

Clinicians should thoroughly and accurately document genital exam findings in the medical record, reserving conclusions and diagnostic terms for the impression and plan portion of the documentation rather than in the description of exam findings. Each structure visualized should be noted (e.g., clitoris, labia majora, labia minora, urethra, vestibule, and rectum) with attention to describing normal appearance and any anatomic variations (e.g., the configuration of the hymen as annular, crescentic, etc.). Describing any findings or lesions using a clock-face method provides a consistent reference point; a sketch or magnified photograph may also be helpful. Future examiners will rely on this documentation as a record with which they compare their findings and note any variances. Changes should be noted in any follow-up examinations.

Adolescents

Some teens prefer to initially meet and discuss the reason for their visit with the provider without their parent or guardian present, and this request should be honored (see Chapter 112). A majority of the time, obtaining a history from an adolescent begins with meeting the patient and her parent or caregiver together to review her history and the reason for the visit and to explain the concepts of confidentiality and privacy. Familiarity with local laws governing limitations to confidential services should guide the protection of the adolescent and her parents' rights to information access and privacy. The Guttmacher Institute provides an up-to-date listing of state and federal laws in the United States affecting access to medical care (http://www.guttmacher.org/statecenter/spibs/index.html). Brief discussions of normal pubertal development and menstruation can reassure both patients and their parents or guardians and provide valuable education on appropriate menstrual flow, menstrual hygiene and the duration and frequency of bleeding. Introducing the menstrual diary as an invaluable tool for the teen can help patients, parents, and clinicians identify abnormal bleeding patterns that might require further evaluation. Many apps are available for tracking menstrual periods on a smart phone or computer.

After the initial interview with the teen and her parent or caregiver, the confidential and sensitive portion of the history, particularly sexual history and alcohol, tobacco, and drug use, is taken with the teen alone. Such a request could be phrased as follows: "I would like to give your daughter an opportunity to ask any questions she might have privately, so would you mind stepping out of the room for a moment?" Concerns for the presence of vaginal discharge, the potential for sexually transmitted infections, pregnancy, or menstrual aberration should be explored. Teens and their parents should be informed of the proper use and accessibility of condoms, all contraceptive methods, and emergency contraception.

A number of resources for educating adolescents regarding their first pelvic examination and in-depth sexual history and psychosocial screening tools are available. These include the North American Society for Pediatric and Adolescent Gynecology (http://www.naspag.org), the American Academy of Pediatrics (http://www.aap.org), the Society for Adolescent Health and Medicine (http://www.adolescenthealth.org), and the American College of Obstetricians and Gynecologists (http://acog.org/Patients).

Pelvic Examination

Table 548-1 presents the indications for the first pelvic examination in adolescents: age older than 21 yr, abnormal uterine bleeding, vulvovaginitis, severe dysmenorrhea, unexplained dysuria or abdominal pain, evaluation and removal of a foreign body, and placement of an intrauterine device. If an adolescent does not meet 1 of the criteria

Table 548-1	Suggested Indications for Pelvic Examination in Adolescents

Age 21 yr for initial Pap test
Unexplained menstrual irregularities, including pubertal aberrations
Severe dysmenorrhea
Unexplained abdominal pain
Unexplained dysuria
Abnormal vaginal discharge
Placement of intrauterine device
Removal of foreign body

Modified from The initial reproductive visit. Committee Opinion No. 460. American College of Obstetricians and Gynecologists. Obstet Gynecol *116:240–243, 2010.*

Table 548-2	Recommendations for First Gynecologic Evaluation

Between 13 and 15 yr of age
First gynecologic encounter focuses on patient education; pelvic examination is generally not indicated
First pelvic examination with Pap test at 21 yr of age, unless otherwise indicated by Table 548-1

Modified from Well-woman visit. Committee Opinion No. 534. American College of Obstetricians and Gynecologists. Obstet Gynecol *120:421–424, 2012.*

listed in Table 548-1, the American College of Obstetricians and Gynecologists recommends that the first gynecologic encounter occur between the ages of 13 and 15 yr (Table 548-2) with attention toward anticipatory guidance focusing on normal pubertal development and menstruation. Patients should undergo screening for sexually transmitted infection with each new sexual partner. With the availability of urine and vaginal swab nucleic acid amplification testing for chlamydia and gonorrhea, sexually transmitted infection screening does not necessitate a speculum exam.

Prior to the initiation of a physical examination, all young women should be offered the choice of having a medical attendant, family member, or friend present during her examination. At the initial gynecologic exam, the physician should explain the process in understandable terms. A thorough evaluation begins with an assessment of body mass index, blood pressure, menstruation status, thyroid, lymph nodes, breast development, abdominal exam, and skin. The external genitals should be examined with the patient in the dorsal lithotomy position while communication is maintained between the physician and patient. Elevating the head of the examination table allows the teen and her examiner to maintain eye contact. The teen can hold a mirror to follow along with the examination, and she should be encouraged to ask questions. Inspection of the vulva is followed by inspection of the Bartholin, urethral, and Skene glands. The clitoris, normally 2-4 mm in width, is then assessed; a clitoris wider than 10 mm, especially in the presence of other signs of virilization, suggests a need for further evaluation. The hymenal anatomy should also be evaluated. Throughout the examination, the proper nomenclature for genital anatomy should be emphasized with the teen to empower her to use proper wordage with the avoidance of slang when referring to her body.

Because the initial Papanicolaou test is deferred until 21 yr of age and cultures for sexually transmitted infections can be obtained from urine or vaginal swabs, the need for a speculum exam is decreasing in this age group. If a speculum exam is indicated, use an appropriate sized speculum, such as the Huffman (½ in wide × 4 in long) or Pedersen (⅞ in wide × 4 in long). Shorter speculums will not allow visualization of the entire vaginal canal. The adolescent patient should be reassured that the exam may be uncomfortable but should not be painful and that her request to stop or wait will be honored. Encouraging the patient to watch with a hand-held mirror facilitates patient education and can be empowering. She may be told before the insertion of the speculum that she will experience a pressure sensation. Before touching the introitus, it may be useful to touch the inner thigh with the speculum. Compression of the urethra anteriorly should be avoided. Gentle pressure with a finger for displacement of the fourchette posteriorly further facilitates proper speculum placement. After visualization of the vagina and cervix, specimens should be obtained as indicated. A bimanual examination, sometimes with a single digit, allows palpation of the vaginal walls and cervix and bimanual assessment of the uterus and adnexa. Reassurance of normal findings throughout the examination should be provided, and normal variants to anatomy should be pointed out to the teen as they are encountered (e.g., asymmetric labia minora).

Following the examination, it is appropriate to review the exam findings with the teen (and her parent) and initiate a collaborative discussion of the management plan. Encouraging the adolescent to participate in decision making empowers her to undertake responsibility for her health, may strengthen compliance with the medical plan, and acknowledge her as a unique individual.

Chapter 549
Vulvovaginitis

Holly R. Hoefgen and Diane F. Merritt

Vulvovaginitis, the most common gynecologic-based problem for prepubertal children, is typically caused by either inadequate or excessive hygiene or chemical irritants. The condition is usually improved by hygiene measures and education of the caregivers and child.

ETIOLOGY

Vulvitis refers to external genital pruritus, burning, redness, or rash. **Vaginitis** implies inflammation of the vagina, which can manifest as a discharge with or without an odor or bleeding. These may occur simultaneously as vulvovaginitis. When a child presents with vulvovaginitis, the history should include questions on hygiene (wiping from front to back) and information about possible chemical irritants (bath soaps, laundry detergents, swimming pools, or hot tubs). The caregiver can be asked about a history of diarrhea, perianal itching, or nighttime itching. The possibility of foreign objects being placed into the vagina should also be asked, although the young child is unlikely to remember or recall. Children are especially prone to nonspecific vulvovaginitis for a variety of reasons, including their nonestrogenized state, poor perianal hygiene, and the proximity of the anus to the vagina, which is without geographic barriers given the flattened labia and lack of pubic hair (Fig. 549-1 and Table 549-1).

EPIDEMIOLOGY

Infectious vulvovaginitis, where a specific pathogen is isolated as the cause of symptoms, may be caused by fecal or respiratory pathogens and cultures might reveal *Escherichia coli* (see Chapter 200), *Streptococcus pyogenes, Staphylococcus aureus* (see Chapter 181), *Haemophilus influenzae* (see Chapter 194), *Enterobius vermicularis,* and, rarely, *Candida* spp. (see Chapter 234). These organisms may be transmitted by the child using improper toilet hygiene and manually from the nasopharynx to the vagina. The children present with perianal redness, an inflamed introitus, and often a yellow-green or mildly bloody discharge. They may be observed to be grabbing their genital area or "digging" in their underwear, which is usually stained with yellow-brown discharge. Attempts to treat these bacterial etiologies with antifungal medication will fail and often the antifungal product will lead to more irritation. Table 549-2 gives specific treatment recommendations based on the bacteria localized.

Neisseria gonorrhoeae or *Chlamydia trachomatis* also are causes of specific infectious vulvovaginitis (see Chapter 120). Management of children who have sexually transmitted infections requires close cooperation between clinicians and child-protection authorities. Official investigations for sexual abuse, when indicated, should be initiated promptly (see Chapter 40). If acquired after the neonatal period, some diseases (e.g., gonorrhea, syphilis, and chlamydia) are virtually 100% indicative of sexual contact. For other diseases (e.g., human papillomavirus infection and herpes simplex virus), the association with sexual contact is not as clear. Presumptive treatment for children who have been sexually assaulted or abused is not recommended because (1) the incidence of most sexually transmitted infections in children is low after abuse/assault, (2) prepubertal girls appear to be at lower risk for ascending infection than adolescent or adult women, and (3) regular follow-up of children usually can be ensured. Although *Trichomonas vaginalis* can be transmitted vertically and can be seen in children up to 1 yr of age, it is an uncommon cause of specific infectious vulvovaginitis in the unestrogenized prepubertal girl.

Figure 549-1 Labial adhesions. *(Photo courtesy of Diane F. Merritt, MD.)*

Other causes of specific infectious vulvovaginitis include *Shigella* (see Chapter 199), which often manifests with a blood-tinged purulent discharge, and *Yersinia enterocolitica* (see Chapter 203). *Candida* infections (yeast) commonly cause diaper rash, but they are unlikely to cause vaginitis in children because the alkaline pH of the prepubertal vagina does not support fungal infections. Exceptions can occur in diabetic or immunocompromised children or children on prolonged antibiotics. Pinworms are the most common helminthic infestation in the United States, with the highest rates in school-age and preschool children. Perianal itching can lead to excoriation and, rarely, bleeding.

CLINICAL MANIFESTATIONS

Diaper Dermatitis

Diaper dermatitis is the most common dermatologic problem in infancy and occurs in half of all diaper-wearing infants and children. The moisture and contact with urine and feces irritates the skin, and colonization with *Candida* spp. increases the severity of the dermatitis. First-line treatment includes hygiene measures such as increasing the frequency of diaper changes, allowing the infant to be diaper free,

Table 549-1 Specific Vulvar Disorders in Children

ORGANISM	PRESENTATION	DIAGNOSIS	TREATMENT
Molluscum contagiosum (Fig. 549-7)	1-5 mm discrete, skin-colored, dome-shaped, umbilicated lesions with a central cheesy plug	Diagnosis usually is made by visual inspection	The disease generally is self-limited and the lesions can resolve spontaneously Treatment choices in children may include cryosurgery, laser, application of topical anesthetic and curettage, podophyllotoxin, and topical silver nitrate Use of topical 5% imiquimod cream and 10% potassium hydroxide has been reported with similar effects
Condyloma acuminata	Skin-colored papules, some with a shaggy, cauliflower-like appearance	Diagnosis usually is made by visual inspection. Biopsy should be reserved for when the diagnosis is in question. Human papillomavirus DNA testing is not helpful	Many lesions in children resolve spontaneously, “wait and see” often utilized in children (60 days). Topical treatment with imiquimod cream and podophyllotoxin is the most studied (daily qhs 3 times/wk × 16 wk, wash 6-10 hr after application). General anesthesia is usually required for surgical/ablative procedures (cryotherapy, laser therapy, electrocautery)–reserve for symptomatic or large lesions. Other treatments have been utilized in adults, including trichloroacetic acid, 5-fluorouracil, sinecatechins, topical cidofovir, and cimetidine. The efficacy and safety of these treatments in children has not been established
Herpes simplex	Blisters that break, leaving tender ulcers	Visual inspection confirmed by culture from lesion	*Infants:* Acyclovir 20 mg/kg body weight IV q8 hr × 21 days for disseminated and central nervous system disease or × 14 days for disease limited to the skin and mucous membranes *Genital/mucocutaneous disease:* Age 3 mo–2 yr: 15 mg/kg/day IV divided in q8h × 5-7 days Age 2-12 yr (1st episode): Same as above or 1,200 mg/day divided in q8h dosing × 7-10 days Age 2-12 yr (Reoccurrence): 1,200 mg/day in q8h dosing or 1,600 mg/day in bid dosing × 5 days (give 3-5 days for children older than 12 yr)

Table 549-1 Specific Vulvar Disorders in Children—cont'd

ORGANISM	PRESENTATION	DIAGNOSIS	TREATMENT
Labial agglutination (see Fig. 549-1)	May be asymptomatic or can cause vulvitis, urinary dribbling, urinary tract infection, or urethritis	Diagnosis is made by visual inspection of the adherent labia, often with a central semitranslucent line	Does not require treatment if the patient is asymptomatic *Symptomatic patients:* Topical estrogen cream or betamethasone ointment applied alone or in combination daily for 6 wk directly to the line of adhesion, using a cotton swab while applying gentle labial traction Estrogen should be interrupted if breast budding occurs Mechanical or surgical separation of the adhesions is rarely indicated The adhesions usually resolve in 6-12 wk; unless good hygiene measures are followed, reoccurrence is common To decrease the risk of recurrence, an emollient (petroleum jelly, A and D ointment) should be applied to the inner labia for 1 mo or longer at bedtime
Lichen sclerosus (Fig. 549-4)	A sclerotic, atrophic, parchment-like plaque with an hourglass or keyhole appearance of vulvar, perianal, or perineal skin, subepithelial hemorrhages may be misinterpreted as sexual abuse or trauma The patient can experience perineal itching, soreness, or dysuria	Diagnosis usually is made by visual inspection Biopsy should be reserved for when the diagnosis is in question	Ultrapotent topical corticosteroids are the first-line therapy (clobetasol propionate ointment 0.05%) once or twice a day for 4-8 wk Once symptoms are under control, the patient should be tapered off the drug unless therapy is required for a flare-up In many girls, the condition resolves with puberty; however, this is not always the case and patients may require long-term follow-up
Psoriasis	Children are more likely than adults to have vulvar psoriasis noted as pruritic, well-demarcated, nonscaly, brightly erythematous, symmetrical plaques. The classic extragenital lesion are similar but with a silver scaly appearance	Diagnosis may be confirmed by locating other affected areas on the scalp or in nasolabial folds or behind the ears	Vulvar lesions may be treated with low to medium potency topical corticosteroids, increasing strength as necessary
Atopic dermatitis	Chronic cases can result in crusty, weepy lesions that are accompanied by intense pruritus and erythema Scratching often results in excoriation of the lesions and secondary bacterial or candidal infection	It may be seen in the vulvar area but characteristically affects the face, neck, chest, and extremities	Children with this condition should avoid common irritants and use topical corticosteroids (such as 1% hydrocortisone) for flare-ups If dry skin is present, lotion or bath oil can be used to seal in moisture after bathing
Contact dermatitis	Erythematous, edematous, or weepy vulvar vesicles or pustules can result, but more often the skin appears inflamed	Associated with exposure to an irritant, such as perfumed soaps, bubble bath, talcum powder, lotions, elastic bands of undergarments, or disposable diaper components	Avoidance of irritant Topical corticosteroids for flare-ups
Seborrheic dermatitis	Erythematous and greasy, yellowish scaling on vulva and labial crural folds associated with greasy dandruff-type rash of scalp, behind ears and face	Diagnosis usually is made by visual inspection	Gentle cleaning, topical clotrimazole with 1% hydrocortisone added
Vitiligo (Fig. 549-5)	Sharply demarcated hypopigmented patches, often symmetric in vaginal and anal regions. May be present in periphery at body orifices and extensor surfaces	Clinical. Test for associated illness if clinically warranted (thyroid disease, Addison disease, pernicious anemia, diabetes mellitus)	If desired, treat limited lesions with low-potency corticosteroids or tacrolimus. See dermatologist for extensive lesions.

Table 549-2 Antibiotic Recommendations for Specific Vulvovaginal Infections

ETIOLOGY	TREATMENT
Streptococcus pyogenes *Streptococcus pneumoniae*	Penicillin V, 250 mg PO bid-tid ×10 days Amoxicillin 50 mg/kg/day (max: 500 mg/dose) divided into 3 doses daily × 10 days Erythromycin ethyl succinate, 30-50 mg/kg/day (max: 400 mg/dose) divided into 4 doses daily TMP-SMX 6-10 mg/kg/day (TMP component) divided into 2 doses daily × 10 days Clarithromycin 7.5 mg/kg bid (max: 1 g/day) × 5-10 days Reoccurrence most likely from asymptomatic pharyngeal carriage in child or family member. However, failure of penicillin regimens can occur For penicillin resistance: Rifampin 10 mg/kg every 12 hr × 2 days
Staphylococcus aureus	Topical mupirocin 2% 3 times daily to the affected skin area If systemic therapy required: Amoxicillin-clavulanate, 45 mg/kg/day (amoxicillin) PO divided into 2 or 3 doses daily × 7 days (first-line treatment because of high penicillin resistance) Extensive resistance to common antibiotics noted, recommend susceptibility testing for further antibiotic use MRSA: TMP-SMX double-strength 8-10 mg/kg/day; culture abscesses, incision and drainage
Haemophilus influenzae	Amoxicillin, 40 mg/kg/day divided into 3 doses daily × 7 days Cases of treatment failure or non-encapsulated *H. influenzae*, amoxicillin–clavulanate is recommended
Yersinia	TMP-SMX 6 mg/kg (TMP component) daily for 3 days
Shigella	TMP-SMX 10/50 mg/kg/day (max: 160/600) divided into 2 doses daily × 5 days Ampicillin 50-100 mg/kg/day divided into 4 doses daily (adult max: 4 g/day) × 5 days Azithromycin 12 mg/kg (max: 500) × 1 day, then 6 mg/kg/day (max: 250 mg) × 4 days (in areas of high resistance to above regimens or when sensitivities are unknown) For resistant organisms: Ceftriaxone 50-75 mg/kg/day IV or IM divided into 1 or 2 doses (max: 2 g/day) × 2-5 days
Chlamydia trachomatis	*Children weighing <45 kg:* Erythromycin base or ethylsuccinate 50 mg/kg/day PO divided into 4 daily doses × 14 days *Children weighing >45 kg but age younger than 8 yr:* azithromycin 1 g PO in a single dose *Children age older than 8 yr (treat per adult regimens):* *Preferred regimens:* Azithromycin 1 g PO in a single dose *or* Doxycycline 100 mg PO twice daily × 7 days *Alternative regimens:* Erythromycin base 500 mg PO 4 times daily × 7 days Erythromycin ethylsuccinate 800 mg PO 4 times daily × 7 days Levofloxacin 500 mg PO daily × 7 days Ofloxacin 300 mg PO twice daily for 7 days
Neisseria gonorrhoeae	*Children weighing <45 kg:* Ceftriaxone, 125 mg IM in a single dose *Children weighing ≥45 kg:* Treat with adult regimen of 250 mg IM in a single dose *Children with bacteremia or arthritis:* Ceftriaxone, 50 mg/kg (max dose for children weighing <45 kg: 1 g) IM or IV in a single dose daily × 7 days *Dual treatment:* Addition of either azithromycin 1 g PO in a single dose or doxycycline 100 mg PO twice daily × 7 days to the above regimens may assist in hindering the development of antibiotic resistance. *Note:* The CDC removed cefixime 400 mg PO in a single dose from recommended medications because of increasing resistance; however, can be used as part of a dual therapy if ceftriaxone is unavailable
Trichomonas	Metronidazole, 15-30 mg/kg/day tid (max: 250 mg tid) × 5-7 days *or* Tinidazole 50 mg/kg (≤2 g) as a single dose for children older than 3 yr
Pinworms *(Enterobius vermicularis)*	Mebendazole (Vermox), 1 chewable 100 mg tablet, repeated in 2 wk *or* Albendazole, 100 mg for child younger than age 2 yr or 400 mg for older child, repeated in 2 wk Pyrantel pamoate 10 mg/kg in a single administration

MRSA, methicillin-resistant *Staphylococcus aureus;* TMP-SMX, trimethoprim-sulfamethoxazole.

frequent bathing, and application of water-repellant barriers such as zinc oxide. If diaper dermatitis persists after these conservative measures, or if the classic satellite lesions of *Candida* are present, treatment with an antifungal can decrease the inflammation.

Physiologic Leukorrhea

Neonates and peripubertal girls can present with a white or clear or mucus discharge, which is a physiologic effect of estrogen. Some girls complain of the moisture and mucus, but an explanation should reassure the patient and her mother.

Genital Ulcers

Acute genital ulceration of the vulva (Fig. 549-2) is described in young adolescents who are not sexually active and can occur in association with oral aphthous ulcers. Although linked to infectious causes such as Epstein-Barr, cytomegalovirus, mycoplasma, and influenza A, recent data suggest these ulcers may be idiopathic vulvar aphthoses.

Other potential etiologies include inflammatory bowel disease, Behçet disease, pemphigoid, Stevens-Johnson syndrome, drug eruption, or mouth and genital ulcers with inflamed cartilage (MAGIC) syndrome.

These lesions usually appear on the mucosal surfaces of the introitus as painful red or white lesions that evolve into sharply demarcated red-rimmed ulcers with a necrotic or eschar-like base. The time course is generally 10-14 days until remission occurs. The lesions are quite painful and pain management and urinary diversion with a Foley catheter may be necessary. Patients with acute genital ulcers show a fairly consistent picture of flu-like prodromal symptoms, dysuria, and

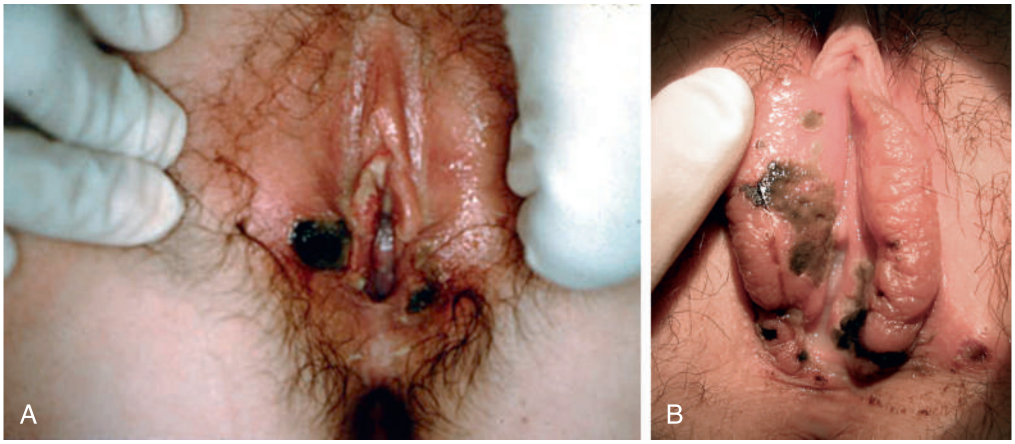

Figure 549-2 Aphthous ulcers. *(Photo courtesy of Diane F. Merritt, MD.)*

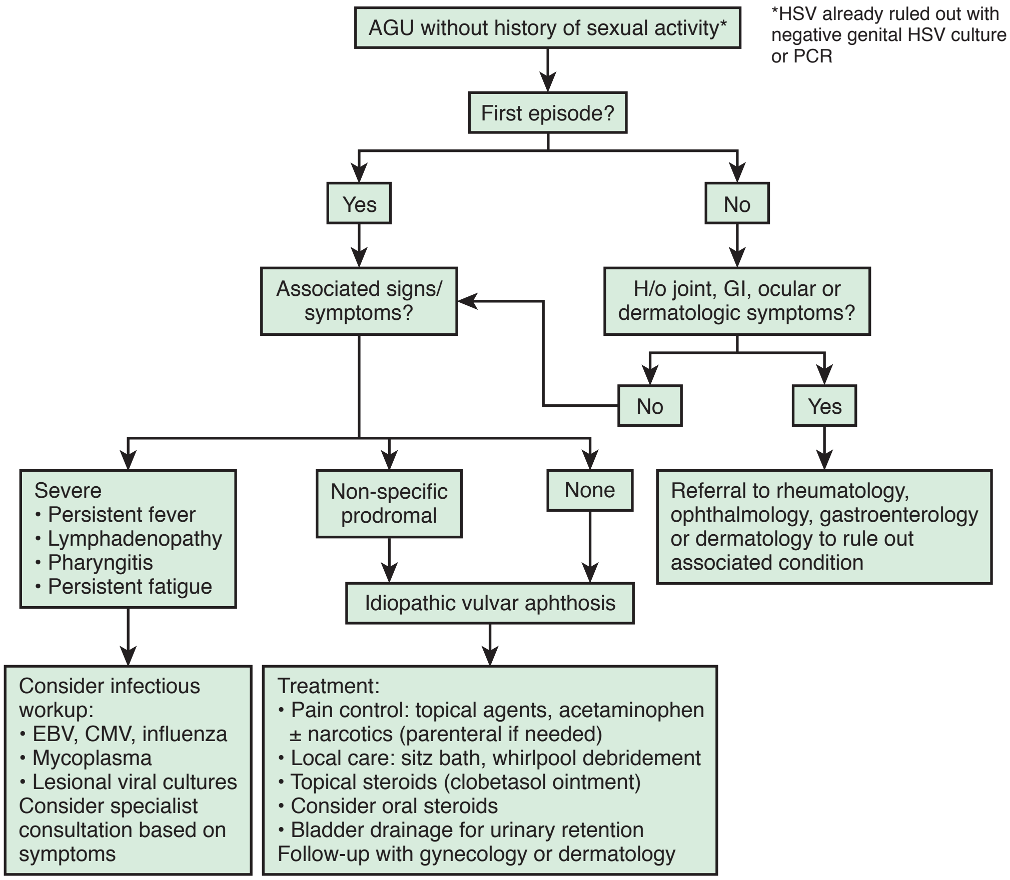

Figure 549-3 Algorithm for evaluation and management of acute genital ulcers in nonsexually active young girls. *(From Rosman IS, Berk DR, Bayliss SJ, et al: Acute genital ulcers in nonsexually active young girls: case series, review of the literature, and evaluation and management recommendations.* Pediatr Dermatol *29(2);147–153, 2012.)*

vulvar pain. One-third of patients present with a history of or develop oral ulcerations. Evaluation includes culture for herpes simplex virus to exclude this etiology. Special testing for systemic disease depends on history. Biopsies are usually nondiagnostic as they yield acute and chronic inflammatory changes. Figure 549-3 outlines suggested evaluation and management for initial and recurrent disease. Evaluation for Behçet disease (see Chapter 161) using the International Study Group diagnostic guidelines should be considered with recurrent or severe cases. (See Table 549-1 for other common etiologies.) Treatment of acute genital ulcers should include topical Xylocaine 2% jelly, sitz baths, good hygiene, and acetaminophen. Nonsteroidal antiinflammatory drug avoidance is suggested because of a possible causative link. Hospitalization may be required for pain management not controlled with oral narcotics, urinary retention requiring Foley catheterization or for whirlpool debridement should hygiene become difficult. Antibiotic treatment is not required unless evidence of bacterial superinfection exists or the patient is immunocompromised. Insufficient evidence exists to recommend whether oral steroid treatment is effective but may be helpful in the setting of recurrent outbreaks. Ultrapotent topical steroids (clobetasol 0.05% ointment), however, are beneficial in oral aphthous ulcers and may prove helpful in acute genital ulcers as well.

Figure 549-4 Lichen sclerosus. *(Photo courtesy of Diane F. Merritt, MD.)*

Dermatoses

Dermatologic conditions often affect the vulvar area in children; it is important to determine if the girl presenting with vulvar irritation has a skin condition elsewhere on the body. Lichen sclerosus is commonly seen in the anogenital region and has a characteristic appearance of white skin changes associated with areas of erosion, ulceration, and petechia. This disease can cause severe discomfort and most commonly presents with vulvar or perianal pruritus, dysuria, and constipation. Patients may also present without any symptoms, which may lead to underrecognition and under treatment. If untreated, lichen sclerosus can lead to destruction and scarring of normal genital architecture, including labial resorption, obliteration of the clitoris, narrowing of the introitus, and painful fissures that may become secondarily infected. Once thought to resolve with puberty, this theory is now controversial and many postmenarchal adolescents still suffer from disease (Fig. 549-4). Lichen sclerosis may be treated with potent topical steroids, clobetasol propionate 0.05% applied once or twice daily until the symptoms resolve.

Vitiligo is an acquired skin depigmentation resulting from an autoimmune process directed at epidermal melanocytes. Lesions appear as sharply demarcated patches of pigment loss, often symmetrically located around vagina and anal area. Similar lesions of hypopigmentation can be found surrounding body orifices and extensor surfaces (Fig. 549-5). Although diagnosis is clinical, there is an association with other autoimmune or endocrine disorders (hypothyroidism, Graves disease, Addison disease, pernicious anemia, insulin-dependent diabetes mellitus) and workup should include evaluation for at least thyroid dysfunction. Mild topical corticosteroid cream or ointment may be prescribed for children. Dermatologists may offer immunomodulators (tacrolimus), and phototherapy.

Vulvar psoriasis presents as pruritic, well-demarcated nonscaly, erythematous, symmetrical plaques that involve the vulva, perineum and/or gluteal folds. Lesions on the mons pubis may have the more characteristic scaly appearance. The classic signs of psoriasis may also be appreciated with pitting nail beds, posterior auricular erythema or a silvery scaling rash found elsewhere on the body. Many of the treatments used in adults may not be appropriate in children. Psoriasis may be treated with moisturizers, topical steroids, and light therapy. Teens may be treated with coal tar, retinoids, tacrolimus, and calcipotriene, which is a derivative of vitamin D_3.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Children with symptoms of vulvovaginitis often have had a previous evaluations and treatment failures. Cultures with sensitivities to test for specific pathogens may be obtained with cotton swabs or urethral (Calgiswab) swabs moistened with nonbacteriostatic saline. Use of a swab can cause discomfort or, rarely, minimal bleeding. The premoistened swab can be placed vertically between the labia minora to collect secretions, as it is not necessary to place the swab into the vagina.

Figure 549-5 Vitiligo. *(Photo courtesy of Diane F. Merritt, MD.)*

Testing for gonorrhea and chlamydia may be done by culture or by nucleic acid amplification testing, depending on institutional or state and Centers for Disease Control guidelines. Tests for *Shigella* and *H. influenzae* might require special media and collection procedures.

If pinworms (see Chapter 294) are suspected, transparent adhesive tape or an anal swab should be applied to the anal region in the morning before defecation or bathing and then placed on a slide. Eggs seen on microscopic examination confirm the diagnosis, and sometimes the pinworms can be seen at the anal verge. Clinical history is often more indicative of disease than physical exam, and a negative tape test does not rule out this pathogen as a cause.

If the vaginal discharge is serosanguineous, if a foul odor is present, or if the discharge fails to respond to hygiene measures, consider presence of a vaginal foreign body (Fig. 549-6). If inspection suggests presence of a foreign body, the vagina can be irrigated, or an examination under anesthesia may reveal the foreign body. Vaginoscopy is an excellent diagnostic tool and can be performed in an unsedated cooperative patient in an outpatient setting, or under general anesthesia if necessary. Using a cystoscope with saline or water irrigation to gravity, insert the endoscopic device into the vagina, gently oppose the labia, the vagina will distend and the entire vaginal cavity and cervix may be easily assessed.

TREATMENT AND PREVENTION

The treatment of specific vulvovaginitis should be directed at the organism causing the symptoms (see Table 549-1). Treatment of nonspecific vulvovaginitis includes sitz baths and avoidance of irritating or harsh soaps and chemicals and tight clothing that abrades the perineum. External application of bland emollient barriers such as nonprescription diaper rash medications and petroleum jelly may be helpful. Proper perineal hygiene is critical for long-term improvement. Younger children need supervised perineal hygiene, and caregivers should be advised to wipe the genital area from front to back. Use of a warm moistened washcloth or diaper wipe is helpful after initially wiping with toilet tissue. Girls should wear cotton underwear and limit time spent in tights, leotards, jeggings, tight jeans, and wet swimsuits. Soaking in warm clean bathwater for 15 min intervals (no shampoo or

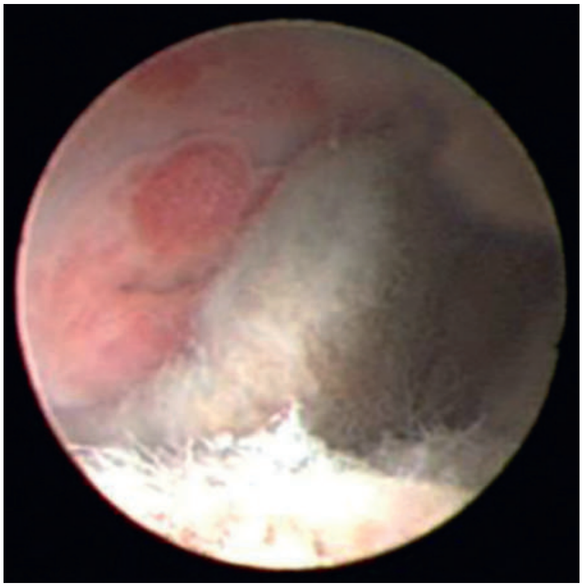

Figure 549-6 Vaginal foreign body as seen through vaginoscope. *(Photo courtesy of Diane F. Merritt, MD.)*

Figure 549-7 Molluscum contagiosum. *(Photo courtesy of Diane F. Merritt, MD.)*

bubble bath) is soothing and helps with cleaning the area. Parents should be counseled to avoid all scented, antiseptic, and deodorant-based soaps, and to eliminate the use of fabric softeners or dryer sheets when laundering undergarments.

Chapter 550
Bleeding
Diane F. Merritt

Vaginal bleeding in infants and prepubescent children should always be evaluated. Bleeding can be seen as early as the 1st wk of life, resulting from endometrial sloughing associated with maternal estrogen withdrawal. A thorough history and physical must be obtained as the 1st step in evaluating the problem. Common causes for vaginal bleeding in children are vulvovaginitis, vaginal foreign bodies, dermatologic conditions, and urethral prolapse; less common causes are endogenous or exogenous estrogenic effects; and the most worrisome causes include neoplasms and trauma.

Vulvovaginitis (see Chapter 549) may be caused by respiratory, oral and fecal pathogens, some of which produce serosanguineous drainage (e.g., *Streptococcus, Shigella*) or cause vulvar bleeding resulting from irritation and excoriation of the skin. Prepubertal girls are at a higher risk for developing these irritations because the protective labia of pubertal girls are not fully developed and thus, the vaginal opening and vagina are easily more exposed to irritants. Further, the hypoestrogenic vaginal mucosa is thin and lacks the protective effects of an acidic pH from lactobacilli. The alkaline vaginal pH noted in prepubertal girls results in an environment more prone to infection. Handwashing, improved perineal hygiene (wiping front to back, use of wet wipes after bowel movement), and avoidance of topical irritants, chemicals, and perfumed or deodorant soaps and bubble baths will reduce nonspecific vulvovaginitis. External application of bland emollient barriers such as over the counter diaper rash ointments or petroleum jelly may helpful (see Table 549-2 in Chapter 549). Antibiotics will help with recurrent or persistent infections if a specific pathogen is identified by culture.

Hematuria is suspected when the urine is red or brown. Gross hematuria may be confused with vaginal bleeding. A positive urinary dipstick can confirm blood, but pigments and metabolites may also cause red or brown urine (see Chapter 509). The cause of gross hematuria in symptomatic children is usually elicited by a complete history, physical examination and urinalysis. Additional diagnostic studies may include ultrasound of the kidneys and bladder, urine culture, measurements of urine calcium/creatinine, and serum C3 and creatinine. Treatment depends on the diagnosis.

Dermatoses may present with bleeding. Lichen sclerosus (see Fig. 549-4 and Table 549-1 in Chapter 549). is characterized by chronic inflammation, intense pruritus, loss of normal architecture, thinning and whitening of the vulvar and perianal skin often in a butterfly or keyhole distribution. Petechiae or blood blisters can arise and be mistaken as a sign of sexual abuse. Diagnosis is based on these classic clinical characteristics, but may be confirmed by a tissue biopsy if necessary. As a first-line treatment, potent topical steroids, such as clobetasol propionate ointment 0.05%,may be applied sparingly to the affected tissue 1-2 times a day under physician supervision; they usually result in improvements in appearance and pruritus. The steroid should be used for the shortest duration necessary then be stopped or tapered. Flare-ups can occur and require retreatment.

Foreign bodies are a common cause of vaginal bleeding, and children present with blood-stained and foul-smelling discharge. The most common object found in prepubertal girls is toilet paper. A physical exam in knee–chest or frogleg position can sometimes reveal the object. Vaginal irrigation may be done in the office setting using a small feeding tube, a syringe, and warm water. If the object is not visible on examination, irrigation is unlikely to remove it and examination under anesthesia and vaginoscopy are often required. Vaginoscopy not only allows removal of a foreign object but also can facilitate diagnosis of other causes of the bleeding.

Trauma to the vulva or vagina is especially concerning. Most of these injuries are accidental, but physical and sexual abuse must be ruled out (see Chapter 40). Straddle injuries such as falling on the cross bar of a bicycle or slipping in the bathtub may result in bruising, hematomas, and lacerations. In general, if the trauma is accidental, the hymen and vagina are spared as most accidental injuries involve the mons and labia. *If there are no eyewitnesses to the injury, if there is no history to explain the clinical findings, and especially if there is a laceration of the hymen, abuse must be considered in the differential diagnosis, and a forensic interview of the patient and family should take place.* If the injury is penetrating, further examination and imaging are necessary to evaluate the urethra, bladder, anus, and intraabdominal structures. General anesthesia may be needed to fully assess injuries and allow adequate repair; while minor lacerations may be repaired in a cooperative child under sedation or local anesthesia. If the patient is able to

void spontaneously, nonexpanding hematomas can be observed and treated with ice, pressure, and pain medications. Large expanding hematomas should be carefully evaluated and may require drainage, ligation of the bleeding vessels, and/or placement of a closed suction drain, especially if the overlying skin is showing signs of necrosis. A Foley catheter should be placed for children who are having difficulty with voiding.

Urethral prolapse (see Chapter 544) is another potential cause of bleeding in the prepubertal girl. The patient may present with a circular protrusion of the urethral mucosa through the external meatus forming a friable vulvar mass. Downward traction at the introitus enables visualization of the vaginal orifice separate from the urethral mass and assists with confirming the correct diagnosis. Patients may be asymptomatic or present with bleeding, dysuria, or difficulty with urination. Low estrogen state, trauma, chronic cough, and constipation are believed to be predisposing factors. Treatment is conservative, with application of estrogen cream at the area of prolapse twice daily for 1-2 wk and then, if prolapse is still present, continued use until the prolapse resolves. Surgical excision is very rarely necessary to remove necrotic tissue.

Neoplasms of the vulva and vagina are rare (see Chapter 553). Infantile hemangiomas are the most common benign vascular neoplasm of infancy, affecting 5% of all infants. Most lesions proliferate then involute, and only a few require intervention. Hemangiomas of the perineum may be associated with spinal dysraphism, so a neurologic assessment should be performed. Intralesion and systemic steroids have been used to treat infantile hemangiomas. Propranolol therapy results in a good response rate. Laser therapy and surgical excision are sometimes used.

Like hemangiomas, hymenal polyps are usually benign. If these polyps are noted at birth, they generally regress after maternal levels of estrogen decrease in the infant. If hymenal polyps persist, grow, or cause discomfort they may be removed. Vaginal polyps, especially if they cause bleeding, should be removed (not followed) and sent for pathologic evaluation. Yolk sac (endodermal sinus) tumors of the vagina are rare but may cause vaginal bleeding. Serum α-fetoprotein is a reliable marker. Rhabdomyosarcoma is the most common soft-tissue sarcoma of childhood. In children, the most common sites are the head and neck (35%) and genitourinary region (25%) (see Chapter 500). Rhabdomyosarcoma arising in the genitourinary tract are commonly the sarcoma botryoides variant and are typically seen in the 1st decade, often before age 3 yr, and present with vaginal discharge and bleeding. Treatment consists of a multimodal approach, including surgery, radiation therapy, and chemotherapy. The survival rate is >90% when an early diagnosis is made.

Vaginal bleeding can be a presenting sign of precocious puberty, which is defined as pubertal development that is 2.5-3.0 SD earlier than the average age. Guidelines for the evaluation of premature development state that pubic hair or breast development requires evaluation generally when it occurs before age 7 yr in non–African-American girls and before age 6 yr in African-American girls (see Chapters 561 and 562). Rapidity of pubertal progression, such as Tanner stage 3 breast development before 8 yr of age, may also require evaluation. The most common etiology is gonadotropin-dependent or central precocious puberty (see Chapter 562.1) where there is premature enhancement of pulsatile gonadotropin-releasing hormone release resulting in ovarian follicle growth and estrogen production. Gonadotropin-independent precocious puberty, where estrogen production is not under hypothalamic control and is produced peripherally, such as from an ovarian/adrenal tumor or McCune Albright syndrome, is less common.

A thorough physical exam must be done, looking for secondary sex characteristics and documenting breast and pubic hair development using the Sexual Maturation Index (Tanner Staging; see Chapter 110.1). Documenting height and weight on a growth chart will assist in identifying accelerated growth velocity. Diagnostic tests include a left wrist x-ray to look for advanced bone age. Elevated serum luteinizing hormone levels are highly suggestive of central precocity, but the gold standard is measurement of gonadotropins after gonadotropin-releasing hormone or gonadotropin-releasing hormone–agonist stimulation. In all cases of central precocious puberty, MRI imaging of the brain is needed to determine if a tumor is present. Pelvic ultrasound might show presence of ovarian or adrenal pathology or uterine maturation in response to estrogen. Benign premature ovarian follicles or malignant ovarian germ cell tumors can produce elevated serum estradiol levels >100 pg/mL. If the estradiol is elevated, pelvic imaging by transabdominal ultrasound is mandated. Usually benign ovarian follicles produce short periods of estrogen elevation which is enough to stimulate the endometrial lining and result in endometrial shedding. Usually by the time the pelvic ultrasound is obtained the follicular structure has collapsed and resolved and the estrogen level has dropped to prepubertal range. If indicated central precocious puberty can be suppressed with leuprolide injections or histrelin implants. Germ cell tumors are treated by excision, staging and chemo or radiation therapy by protocols provided by oncologists.

Juvenile hypothyroidism commonly causes pubertal delay. Patients with severe, long-standing and untreated hypothyroidism may present with premature breast development, vaginal bleeding and abdominal distention resulting from ovarian enlargement and possibly ascites associated with deceleration of linear growth. A proposed mechanism is thyroid-releasing hormone–associated elevations of thyroid-stimulating hormone crossreacting with follicle-stimulating hormone resulting in follicle maturation and estradiol production. Treatment of the hypothyroidism results in improvement and reversal of symptoms.

Another etiology for childhood vaginal bleeding is exogenous exposures to estrogens. These exposures can occur from ingestion of birth control pills, foods, beauty products, and plastics that contain estrogen or estrogen-like components. Several other studies have assessed the risk of bisphenol A leaching from plastic cups and bottles. The importance of this is still being studied, but bisphenol A is known to have an estrogenic effect and thus could potentially be a cause for vaginal bleeding if ingested in high levels.

Vaginal bleeding in the prepubertal girl or infant can have many causes, which range from benign to malignant. A thoughtful history and physical examination must be done to identify the source of bleeding so that treatment can occur. The risk benefit of any therapy should be reviewed carefully with the family.

Chapter 551

Breast Concerns

Kora N. Felsch and Diane F. Merritt

Presenting concerns of girls with breast disorders typically including the development or appearance of their breasts, breast pain, nipple discharge, or concerns about the presence of a mass. Although children and adolescents are very unlikely to have malignant or life-threatening breast problems, this population of patients should be referred to practitioners who have experience and familiarity with the immature and developing breast to avoid overtreatment with unnecessary diagnostic or surgical procedures.

BREAST DEVELOPMENT

Development of the breast begins around wk 5 of gestation, when the ectoderm on the anterior body wall thickens into 2 ridges known as the *mammary ridges*. They extend from the area of the developing axilla to the area of the developing inguinal canal. The ridge above and below the area of the pectoralis muscle recedes in utero, leaving the mammary primordium, which is the origin of the lactiferous ducts.

The initial lactiferous ducts form between wk 10 and 20 and become interspersed through the developing mesenchyme, which becomes the fibrous and fatty portions of the breast. The breast bud, under the stimulation of maternal estrogen, becomes palpable at wk 34 of gestation. This breast bud regresses within the 1st mo of life, because the estrogen stimulation is no longer present. The areola appears at 5 mo of gestation, and the nipple is seen shortly after birth. It is initially depressed and later becomes elevated.

Thelarche, or the onset of pubertal breast development, is hormonally mediated and normally occurs between the ages of 8 and 13 yr, with an average age of 10.3 yr. The initiation of thelarche and progression in females is affected by race, with normal thelarche occurring earlier in African-American girls than in white or Asian girls. This occurs when the hypothalamus releases gonadotropin-releasing hormone, which stimulates the pituitary gland to produce follicle-stimulating hormone and luteinizing hormone, which then stimulates the ovaries to produce estrogen. The estrogen leads to breast development.

Once thelarche is initiated, normal development of the breast occurs over 2-4 yr and is classified by the **sexual maturity rating** system (also known as Tanner Staging) into 5 stages (Chapter 110.1). Maturation can sometimes occur asymmetrically owing to fluctuation of the hormonal environments and various end organ sensitivities. Lack of development by age 13 yr is considered delayed and warrants endocrinology evaluation. Menarche usually occurs approximately 2 yr after initiation of breast development.

BREAST EXAMINATION

A breast examination should be included in the annual examination of all children and adolescents. Examination of the *newborn* includes assessment of breast size, nipple position, presence of accessory nipples, and nipple discharge. Examination of the *prepubertal girl* includes inspection and palpation of the chest wall for masses, pain, nipple discharge, and signs of premature thelarche. Examination of the *adolescent* is performed with the patient in the supine position; the arm ipsilateral to the breast that is being examined should be placed next to the patient's head. The breast tissue is examined with the flat pads of the middle fingers and the examiner can feel for abnormalities on the breast with a pattern similar to spokes on a wheel, in a circular clockwise pattern with concentric circles or by moving in a rotary fashion around the breast. Whatever the method used, the goal is to palpate all the breast tissue in a uniform fashion. The sexual maturity rating should be noted and axillary, supraclavicular, and infraclavicular nodes evaluated for lymphadenopathy. The areola should be compressed to assess for nipple discharge.

BREAST SELF-EXAMINATION

Controversy exists as to the utility of breast self-examination in the adolescent population. Experts believe that it might be ill advised to encourage breast self-examination in the adolescent because of a potential for unnecessary anxiety and possible unwarranted treatment in a population that is at low risk for malignant disease. The American College of Obstetricians and Gynecologists states that despite a lack of definitive data for or against breast self-examination, breast self-examination may be recommended beginning at age 19 yr. Women with previous exposure to *therapeutic chest radiation* therapy are advised to begin breast self-examination 8 yr after radiation therapy.

ABNORMAL DEVELOPMENT

Neonatal Breast Abnormalities

The condition in which breasts enlarge in the newborn period is *neonatal breast hypertrophy*. This is quite common in term infants of either sex and can occur as a result of elevated circulating maternal endogenous steroid hormones in late gestation. As maternal estrogen levels fall, prolactin levels can increase and the breasts can produce a clear or cloudy (milk-like) nipple discharge ("witch's milk") in male and female infants. Repeated manipulation of the breast can exacerbate the condition. On occasion, the hypertrophy is associated with mastitis caused by a staphylococcal or streptococcal infection; antibiotics should be administered.

Precocious Puberty

Premature thelarche is usually an isolated condition and is more common than previously thought. In one study, patients with a sexual maturity rating 2 or greater at 7 yr of age were 10.4% of white, 23.4% of black non-Hispanic, and 14.9% of Hispanic girls. However, it may also be the first symptom of precocious puberty. Precocious puberty occurs in 14-18% of girls with premature thelarche (see Chapter 562). Serial examinations, with particular emphasis on growth velocity, secondary sex characters such as pubic hair, pigmentation of the labia or areola, or vaginal bleeding are imperative to identify precocious puberty. Unless there are associated signs of precocious puberty, the parents should be reassured and the child should be followed.

Amastia

Complete absence of the breast, or amastia, is rare and is thought to occur from lack of formation or obliteration of the mammary ridge. Amastia is usually unilateral and can be congenital or associated with systemic disorders (e.g., ectodermal dysplasia, Crohn disease) or endocrine disorders (e.g., congenital adrenal hyperplasia, gonadal dysgenesis, hypogonadotropic hypogonadism). Novel gene mutations have been discovered that may be linked to syndromic amastia, including *PTPRF*, a protein tyrosine receptor type F gene, and ectodysplasin A receptor *(EDAR)*. It can be associated with anomalies of the underlying mesoderm, such as abnormal pectoralis muscles seen in Poland syndrome (aplasia of the pectoralis muscles, rib deformities, webbed fingers, and radial nerve aplasia) (Fig. 551-1). Amastia or hypomastia can also be iatrogenic, resulting from injuries sustained during thoracotomy, chest tube placement, radiotherapy, severe burns, and inappropriate biopsy of the breast bud. Treatment is surgical correction.

Polymastia and Polythelia

Supernumerary breast tissue (polymastia) and accessory nipples (polythelia) occur in approximately 1-6% of the population (Fig. 551-2). The abnormally placed tissue can be seen anywhere along the mammary ridges as a result of incomplete involution but is usually noted on the chest, upper abdomen, or just inferior to the normally positioned breast. There is an association between polythelia and anomalies of the urinary and cardiovascular system. Surgical excision of the accessory breasts or nipple is not usually needed. Resection of accessory tissue may be warranted if the patient has pain or for cosmetic reasons.

Breast Asymmetry and Hypomastia

Some degree of asymmetry is normal in women, and it may be more pronounced during puberty while the breasts are developing.

Figure 551-1 Preoperative frontal view of a patient with left breast hypoplasia secondary to Poland syndrome. *(From Sadove AM, van Aalst JA: Congenital and acquired pediatric breast anomalies: a review of 20 years' experience,* Plast Reconstr Surg *115:1039–1050, 2005, Fig. 13A.)*

Ovarian granulosa cell tumor	Cannabis
Ovarian follicular cysts	

From Desilva N, Brandt M: Breast disorders in children and adolescents. In Sanfilippo J, Lara-Torre E, editors: Clinical pediatric and adolescent gynecology, *London, 2008, Taylor & Francis.*

Hypoplasia of the breasts varies in degree from a nearly total absence of breast tissue to well-formed breasts that are considered by the patient to be too small. There are several causes for poor or absent breast development. The onset of breast development may be delayed with normal secondary sex characters; the breasts develop slowly but are normal in all other respects; a patient's family history might include late breast development. Other causes include ovarian dysfunction, hypothyroidism, and chest wall irradiation or surgery. Hypoplastic breast tissue can also be associated with a tuberous breast anomaly. Treatment depends on the underlying cause. Patients with mild asymmetry and with no other associated pathology should be reassured. Surgical correction is an option for women with marked asymmetry but should be delayed until after puberty.

Juvenile or Virginal Hypertrophy

Spontaneous massive growth of the breasts during puberty and adolescence is thought to be the result of excessive end-organ sensitivity to gonadal hormones, although both the hormone receptors and serum estradiol levels are normal. The underlying cause, if any, should be determined and removed (Table 551-1). When growth is extreme it is termed *macromastia* or *gigantomastia.* It is more commonly bilateral, often occurs over a brief period, and most commonly affects adolescent girls (Fig. 551-3). Physical and psychologic problems can affect posture and quality of life. Strong emotional support should be provided as this can affect an adolescent's self-esteem at a vulnerable time in her psychologic development. Management should be individualized and may range from reassurance or the use of supportive brassieres to reduction mammoplasty or even mastectomy. Medical therapy, such as tamoxifen, is available to slow breast growth in extreme cases until surgery can be performed. Surgical intervention often necessitates relocation of the nipple, which can result in decreased sensation and altered lactation, and it is not uncommon for the lesion to recur.

INFECTIONS

Mastitis is the most common infection of the breast. Although it is most common in lactating mothers, it can occur in young infants and adolescents. Neonatal mastitis is an infection that usually occurs in term or near-term infants. It should be treated aggressively to reduce the risk of forming abscesses. Adolescents can develop nonlactational mastitis or a breast abscess for unknown reasons, as a result of irritation of the skin (through shaving or nipple stimulation), trauma, a foreign body (e.g., piercing), ductal abnormality (such as ductal ectasia), or infection of an epidermal cyst. The initial therapy of all breast infections is antibiotics and analgesics. *Staphylococcus aureus* (see Chapter 181.1) or anaerobic bacilli (*bacteroides*) are the offending organism is almost all cases, and methicillin-resistant *S. aureus* coverage should be considered in communities where prevalence is high. Owing to the potential for breast abscess, the neonatal population should be treated with parenteral antibiotics for methicillin-resistant *S. aureus* or guided by gram stain, when available. Adolescents may be initially treated with warm compresses and oral antibiotics. Abscesses should be surgically evaluated (with ultrasound guidance if necessary) and drained as necessary. If incision and drainage is performed, a small, periareolar incision is indicated.

TRAUMA AND INFLAMMATION

Breast trauma is common in adolescent girls participating in contact sports. The trauma usually takes the form of contusion or hematoma and can resolve spontaneously or may be associated with late cystic changes in the breast or fibrosis with retraction of the skin or the nipple over the injured area.

NIPPLE DISCHARGE

Nipple discharge must be carefully evaluated and a distinction made among galactorrhea (milky white discharge), blood, or other discharge (Table 551-2). A careful history and physical examination directed at the possible etiologies of galactorrhea will help the practitioner determine the etiology. Examination of the discharge assists in diagnosis. Benign conditions are usually associated with a milky, sticky, thick discharge; infection is associated with a purulent discharge; intraductal papilloma and cancer are associated with a serous, serosanguineous, or bloody discharge. Preoperative evaluations by mammography, hemoccult, ductography, and cytology are poor predictors of histologic diagnosis. Therefore, patients with pathologic nipple discharge should undergo biopsy for accurate diagnosis.

Galactorrhea

Cytologic evaluation of nipple discharge is not recommended. Serum pregnancy testing and prolactin and thyroid levels are obtained to rule out the presence of a thyroid abnormality, a pituitary prolactinoma, and pregnancy (in the postpubertal adolescent). If the prolactin level

Table 551-2 Common Causes of Nipple Discharge
Pregnancy
Medicines
Hormones (oral contraceptives, estrogen, progesterone)
Blood pressure drugs (methyldopa, verapamil)
Tricyclic antidepressants
Tranquilizers (antipsychotics)
Antinausea drugs (metoclopramide)
Herbs (nettle, fennel, blessed thistle, anise, fenugreek seed)
Illicit drugs (marijuana, opiates)
Stimulation of the breast (sexual or from exercise)
Thyroid abnormalities
Chronic emotional stress
Hypothalamic tumors
Chest wall conditions
Herpes zoster
Trauma
Burns
Tumors
Breast conditions
Mammary duct ectasia
Chronic cystic mastitis
Intraductal cysts
Intraductal papillomas

is elevated, visual field studies and a head MRI might reveal presence of a pituitary adenoma (see Chapter 560). Treatment is directed by results of history, physical exam, and lab studies. Patients should be instructed to avoid nipple stimulation and stop any offending drugs. Hypothyroidism should be treated and prolactin tumors managed with appropriate medical or surgical care. Treatment of galactorrhea (not thyroid related) consists primarily of dopamine agonists such as bromocriptine or cabergoline. Surgical intervention, usually transsphenoidal hypophysectomy, is rarely required.

Bloody Discharge

In adolescent athletes, bloody discharge may be due to chronic nipple irritation (jogger's nipple), discharge from the ducts of Montgomery (on the edge of the areola, not through the nipple) or duct ectasia. Cytologic assessment should be performed. Surgical consultation for a mass is indicated because intraductal breast papillomas have occurred in adolescents. However, there have been no reported cases of breast cancer in infants. Bloody nipple discharge in infants is most likely from mammary duct ectasia, and if the following studies are normal (prolactin, estradiol, thyrotropin, and ultrasound) then watchful waiting may be appropriate.

MASTALGIA

The most common causes of breast pain in adolescents are exercise and benign breast changes. Physiologic swelling and tenderness occur on a cyclic basis, most commonly during the premenstrual phase, and are secondary to hormonal stimulation and resulting proliferative changes. Hormonal imbalance can cause exaggerated responses in the breast tissue, especially in the upper and outer quadrants. Nodularity, poorly localized tenderness, and a soreness radiating to the axilla and arm are usual accompanying findings. The preferable term for these changes is *benign breast changes* rather than fibrocystic disease. Treatments recommended for this condition and exercise-induced pain include a firm supportive sports-type bra, heat, and analgesics. Oral contraceptives often improve the breast pain. A course of nonsteroidal antiinflammatory drugs is also effective. Methylxanthines (caffeine in coffee, tea, carbonated drinks) and smoking should be eliminated. Evening primrose oil and vitamin E are popular but unproven treatments.

BREAST MASSES

Peripubertal Masses

A mass in the developing breast can be of concern to the adolescent and her family. Initial breast development at the onset of thelarche can be asymmetric and thus mistaken for a "mass." The breast bud is palpable in these cases and should be distinguishable. Such asynchronous thelarche should be recognized to avoid biopsy and potential injury to the maturing breast. If there is any question, ultrasound can be used to evaluate for a mass. Unilateral thelarche has also been reported as a side effect of cimetidine and is reversible when the medication is stopped.

In Emans SJ, Laufer MR, Goldstein DP, editors:* Pediatric and adolescent gynecology, *ed 6, Philadelphia, 2012, Lippincott Williams & Wilkins, pp. 405–420.*

Common Adolescent Breast Masses

Table 551-3 shows the differential diagnosis for breast masses in the adolescent patient. The patient should be questioned about the variation in symptoms with the menstrual cycle, associated symptoms such as nipple discharge, recent trauma to the breast, family history of breast masses or cancer, and history of chest radiation or malignancy. Because breast cancer in the adolescent is extremely rare, masses can be expectantly managed for extended periods with little concern for malignancy in this population.

The most common solid mass seen in adolescent girls is the **fibroadenoma**. Fibroadenomas are most often located in the upper outer quadrant of the breast. The average size is 2-3 cm, and 10-25% of patients have multiple lesions. The physical examination is usually diagnostic because these lesions are well circumscribed, rubbery, mobile, and not tender. In equivocal cases, an ultrasound may be helpful in making the diagnosis. Mammography is not indicated in the adolescent patient.

Fibroadenomas can develop because of a local exaggerated response to estrogen stimulation, and they can enlarge during the menstrual cycle. These lesions may be safely watched for at least 2 menstrual cycles, and some investigators suggest observation until adulthood. Approximately 10% of fibroadenomas regress spontaneously. The option of expectantly managing the patient until adulthood should be considered because the risk of primary cancer is very low in this population. If expectant management is chosen, serial ultrasounds every 6-12 mo may be done to ensure that the mass does not have malignant characteristics on imaging and that it is not enlarging or changing in contour until it starts regressing at which time the ultrasounds can be done on longer intervals. Approximately 4% of fibroadenomas grow, and so fine-needle aspiration or excision is recommended when a mass is enlarging, grows >5 cm (because of the risk of giant fibroadenoma or **cystosarcoma phyllodes**), or the mass is causing anxiety to the

patient or her family. Combined estrogen-progesterone birth control pills have been found to be protective of fibroadenomas.

Cysts are very common masses seen in the pediatric breast. Cysts vary in size over the course of a menstrual cycle, so a patient with a possible cyst should be reexamined a few weeks after the initial evaluation to see if the mass is still present. If a mass persists, then it may be imaged by sonography or aspirated with a needle to evaluate if it truly is a cyst. Aspirated fluid that is clear may be discarded. Bloody fluid and other aspirated material should be sent for cytology. Cystic lesions that resolve with aspiration should be reevaluated in 3 mo. If they recur they should be evaluated with sonography.

Malignant Masses

Primary breast cancer is extremely rare in adolescents. Surveillance Epidemiology and End Results data from 1975-2009 establishes an incidence of invasive breast cancer of 0.2/100,000 for females ages 15-19 yr and 1.6/100,000 for females ages 20-24 yr. Although malignancy is rare, lesions with suspicious imaging findings or progressive growth should undergo cytologic or histologic examination. A small study in Austria noted a 4.7% malignancy rate among palpable masses in teens.

Cystosarcoma phyllodes can occur in adolescents and has been reported in a child as young as 10 yr old. It is characterized by asymmetric breast enlargement in association with a firm, mobile, circumscribed mass. It can mimic a giant fibroadenoma. The tumor often grows rapidly and can become quite large. The majority of these tumors have a favorable prognosis, but malignant cystosarcoma phyllodes has been reported to recur both locally and with metastases. Fatal metastatic cystosarcoma phyllodes in an adolescent has occurred. Excision with 1 cm margins is the preferred initial therapy in adolescent patients, regardless of the histologic classification of the lesion.

Juvenile papillomatosis is a marker for increased breast cancer risk in family members, and in patients with these, up to 15% may have a juvenile secretory carcinoma. Treatment of juvenile papillomatosis is total resection of the lesion with preservation of the breast.

Secondary cancers in adolescents with previous therapeutic radiation to the chest or with malignancies with the potential to metastasize to the breast should be monitored more closely for breast masses. Rhabdomyosarcoma is the most common to metastasize to the breast. Breast tumors also may be the first manifestation of relapse (extramedullary) in acute lymphoblastic leukemia.

Imaging of Breast Masses

Because the dense breast tissue of the adolescent obstructs the visualization of a palpable mass, mammography is not advised for this age group. Ultrasonography is the imaging modality of choice for breast abnormalities in the pediatric population. Color Doppler ultrasound can be useful in evaluating breast abnormalities such as fibroadenomas or abscesses.

Recommendations for Daughters of Women with Breast Cancer

Risk Reduction

There are a limited number of things that young women can do to lower their risk of breast cancer. The American Cancer Society recommends regular physical activity, limiting alcohol, and maintaining a healthy weight. Breastfeeding has a slight effect on breast cancer risk and that effect is only among women who have breastfed for a long time. Breastfeeding seems to be more protective against the most aggressive types of breast cancer, including tumors in women with mutations in the *BRCA-1* gene, hormone-receptor negative, and possibly triple-negative tumors.

Screening Procedures

Breast self-examination is an option for women starting in their 20s. Women should be told about the benefits and limitations of breast self-examination. Women should report any breast changes to their health professional. Women in their 20s and 30s should have a clinical breast exam as part of a periodic (regular) health exam by a health professional, at least every 3 yr. After age 40 yr, women should have a breast exam by a health professional every year and a screening mammogram every year and should continue to do so for as long as they are in good health.

Genetic Testing in Children

Genetic testing for mutations in cancer susceptibility genes in children is particularly complex. Both parents and providers may request or recommend testing for minor children; however, many experts (including the American Society of Clinical Oncology) recommend that unless there is evidence that the test result will influence the medical management of the child or adolescent, genetic testing should be deferred until legal adulthood (18 yr or older) because of concerns about autonomy, potential discrimination, and possible psychosocial effects.

COSMETIC SURGERY

A dramatic increase in adolescents desiring breast augmentation has occurred since the turn of the century. Breast augmentation in adolescents is discouraged owing to associated psychologic and physical immaturity. The American Society of Plastic Surgeons discourages breast augmentation in girls younger than age 18 yr for purely cosmetic reasons. The FDA also considers breast implants in adolescents younger than age 18 yr for solely cosmetic reasons to be an off-label use.

Breast reduction surgery might be considered when an adolescent is bothered by extremely large breasts that result in neck and back pain and prevent participation in sports. Breast reduction allows these girls to feel less self-conscious, have less pain, and be more active. Also girls with marked asymmetry in breasts from the pathologies noted earlier can feel self-conscious and request breast surgery. Before performing breast-altering surgery, practitioners must ensure proper selection of teens and families who have an appropriate understanding of the risks and benefits of surgery and realistic expectations of the procedure.

Chapter 552

Polycystic Ovary Syndrome and Hirsutism

Mark Gibson and Heather G. Huddleston

POLYCYSTIC OVARY SYNDROME

Etiology and Definition

Polycystic ovary syndrome (PCOS) is a common disorder of reproductive hormone function that is characterized by the triad of oligoovulation or anovulation, clinical or biochemical hyperandrogenism, and ovaries with a polycystic morphology on ultrasound examination (≥12 follicles in 1 ovary and/or ovarian volume >10 mm^3). Various expert bodies prioritize these elements differently for establishing the diagnosis, and few require the presence of all 3 (Table 552-1). Hyperandrogenism with ovulatory dysfunction (with exclusion of other causes) is most often considered sufficient for diagnosis in the United States. Abnormalities commonly associated with PCOS include obesity, insulin resistance, and the metabolic syndrome, but the phenotype is variable and affected individuals may display none of these. The disorder, affecting 5-8% of women of reproductive age, typically emerges in adolescence when a normal menstrual pattern is not established and there is clinical evidence of androgen excess.

Pathology Pathogenesis and Genetics

PCOS has a high concordance rate in twins, and in some studies either epigenetic or dominant inheritance patterns are observed. Nonetheless, a consistent hereditary pattern has not been identified.

Gonadotropic dysregulation with increased luteinizing hormone (LH) pulsatility and abnormally high ratios of circulating LH to follicle-stimulating hormone (FSH) are found in many patients with PCOS. Increased *ovarian* production of androgen in response to LH and impaired folliculogenesis owing to lower FSH are attributed to this gonadotropic pattern. Abnormal regulation of gonadotropin-releasing hormone agonist and abnormal gonadotropin secretion more likely reflect the abnormal hormonal milieu of the syndrome than explain its origin (Fig. 552-1). An increased ratio of circulating levels of LH : FSH is *not* a diagnostic criterion for PCOS.

Alterations in activities of steroidogenic enzymes that would explain *ovarian androgenic* hyperfunction are seen in PCOS subjects, but they are not consistently present in all patients and it is unclear whether these alterations are a cause of PCOS or are a consequence of ovarian dysregulation. The mass of ovarian stromal cells responsible for androgen production is increased, and surgery that reduces this ovarian component (ovarian wedge resection, or laparoscopic ablative procedures) reduces circulating androgen levels and often restores ovarian cyclicity. Patients with hyperandrogenic congenital or adult-onset adrenal hyperplasia exhibit PCOS-like ovarian dysfunction that can be reversed by reducing the *adrenal-derived* androgens with glucocorticoid therapy. A primary role for androgen excess in the pathophysiology of all instances of PCOS seems unlikely; many patients have minimal hyperandrogenism, and elimination of androgen excess (with gonadotropin-releasing hormone agonists) does not affect associated insulin resistance.

Measures of insulin resistance are greater and more prevalent among women with PCOS than controls even when accounting for body mass index (BMI). Insulin enhances ovarian androgen production directly and contributes to elevations of free testosterone levels through its suppression of hepatic production of sex steroid–binding globulin. Treatment with insulin sensitivity–enhancing agents that can reduce insulin levels is associated with modest reductions in measures of androgen excess and, in some patients, restoration of regular ovulation. The association of insulin resistance with weight might explain the appearance of features of PCOS among some women who gain weight as well as the resolution of PCOS among affected women who lose weight.

Clinical Manifestations

PCOS, a lifelong disorder, commonly becomes manifest as puberty progresses, but its onset can occur later during young adulthood.

PCOS, polycystic ovary syndrome.
From Norman RJ, Dewailly D, Legro RS, et al: Polycystic ovary syndrome, Lancet *370:685–696, 2007.*

Clinical hallmarks are menstrual abnormalities and manifestations of *hyperandrogenism* but the severity of the disorder is variable (Table 552-2). Ovulation is typically irregular or absent, and menses are consequently irregular or absent. When menstrual bleeding does occur, it may be anovulatory bleeding, which is often heavy and/or protracted as a result of an extended period of unopposed endometrial growth. Alternatively, bleeding can be relatively normal in character as a consequence of a preceding ovulation. Protracted spells of anovulation, with accompanying unopposed estrogen is a risk factor for endometrial hyperplasia, and more severe premalignant and frankly malignant changes may eventuate.

The diagnosis of PCOS in adolescents may be made on the basis of a lack of resolution of the normal pattern of anovulatory menstrual cycles present in the 1st 2 postmenarchal years. Less commonly, the diagnosis is made in the setting of primary amenorrhea. Serum androgen levels may be elevated and clinical findings of androgen excess are common, although distinction of normal androgenic expressions of puberty (acne, mild hirsutism) from early manifestations of PCOS may be difficult and serum hormonal testing may be helpful.

Obesity is common among affected women, and in some patients expression of PCOS features is conditional on elevation of BMI and reversible with weight loss. However, there is a subset of patients present with a "lean" PCOS phenotype and thus absence of excess weight should not preclude consideration of the PCOS diagnosis. PCOS is associated with an increased prevalence of insulin resistance and type 2 diabetes independent of the tendency for many affected patients to have an elevated BMI. Additionally, PCOS confers a substantial and specific increase in risk for metabolic syndrome (hyperlipidemia, insulin resistance, type 2 diabetes) in adolescent girls after accounting for BMI.

Laboratory Findings, Diagnosis, and Differential Diagnosis

The diagnosis of PCOS requires exclusion of disorders that would otherwise account for hyperandrogenism and anovulation. Serum 17-hydroxyprogesterone should be measured when there is clear androgen excess to screen for adult-onset 21-hydroxylase deficiency (see Chapter 576). In the adolescent with amenorrhea but minimal hyperandrogenic findings, consideration should be given to functional hypothalamic suppression as a result of excessive exercise and/or dieting, and a careful history taken to rule out such behavioral patterns. All patients should be clinically evaluated for Cushing syndrome, and biochemical evaluation is indicated when findings, including hypertension and/or characteristic body habitus features, are suggestive (see Chapter 577). The 2 disorders have in common a tendency for overweight and varying degrees of insulin resistance and androgen excess, but they differ in that Cushing syndrome demonstrates muscle wasting as a result of catabolism.

Evidence for androgen excess that is rapid in onset and/or severe especially if masculinizing, warrants measurement of androgens (total testosterone, dehydroepiandrosterone [DHEAS]) to exclude the possibility of an androgen-secreting adrenal or ovarian tumor. The laboratory evaluation is completed with the exclusion of hyperprolactinemia, premature ovarian failure, and thyroid disease as causes of anovulation: determinations of functional hyperprolactinemia, FSH, and thyroid-stimulating hormone, respectively.

The diagnosis of PCOS is confirmed from the constellation of oligoovulation or anovulation, androgen excess (clinically or with biochemical confirmation), and typical ovarian morphology on ultrasound. Various experts weigh these 3 features differently and do not, as a rule, require the presence of all (see Table 552-1). Young women often exhibit the ovarian appearance of PCOS without any other evidence, and not all patients with PCOS by the criteria of hyperandrogenism and ovulatory disruption exhibit ovarian changes typical of PCOS. Ultrasound study to diagnose PCOS is not always required if oligoovulation and features of androgen excess are present. Clinical androgen excess (particularly acne) often appears in late puberty and does not necessarily signal PCOS. Nevertheless, young women with persistent oligoovulation or anovulation, accompanied by androgen excess, will likely have persistence of these symptoms and should be considered to have PCOS.

Insulin resistance is common among women with PCOS, and although not requisite for diagnosis, should be considered when PCOS is likely. Adolescents with hyperandrogenemia and anovulation should be evaluated for diabetes or impaired glucose tolerance with a 2 hr (75 g glucose load) glucose tolerance test.

Complications and Long-Term Outlook

Fertility management, prevention of endometrial cancer, and reduction in the likelihood and severity of the common accompanying metabolic disorders are long-term tasks for the PCOS patient and her healthcare providers (Table 552-3). Notwithstanding its reversibility with weight loss in some patients and a tendency to ameliorate in some women later in reproductive life, PCOS usually requires management throughout the reproductive years. Young patients should be counseled that modern fertility management allows most affected women to have children without great difficulty, and they should also know that the disorder does not confer reliable protection from unintended pregnancy. Endometrial cancer can develop as early as the 3rd decade in women with PCOS who are not managed with progestins or ovulation induction; patients should understand the importance of long-term strategies for endometrial protection. Impaired glucose tolerance, type 2 diabetes, and metabolic syndrome are more common among obese adolescents with PCOS; their prevalence increases over time. Weight control through diet and lifestyle measures, detection and management of impaired glucose tolerance and diabetes, and management of abnormal lipids are targets for long-term management.

Treatment

Management focuses on the menstrual abnormalities, symptoms of androgen excess, and associated metabolic changes. Weight loss through lifestyle change, use of hormonal contraceptive agents for menstrual regulation as well as androgen suppression, antiandrogens as adjuncts for hirsutism treatment, and insulin-sensitizing agents are common components of treatment.

Lifestyle Changes

Several studies have shown that comprehensive lifestyle programs for overweight and obese *women* with PCOS aimed at fitness and weight loss can yield high rates of restoration of normal menstrual function, reduction of free androgen index, reduction in measures of insulin resistance, and improvements in serum lipids. Limited data show similar benefits from such interventions for obese *adolescents* with PCOS. Successful weight loss programs for adolescents with PCOS using both psychologic and nutritional counseling do result in improved menstrual function.

Hormonal Contraceptives

Combined (estrogen and progestin) hormonal contraceptive medications are considered first-line therapy for adults not desiring fertility and for adolescents (see Chapter 117). Adolescents with PCOS are at risk for unintended pregnancy; their fertility would be expected to be reduced relative to that of their peers, but they are still at risk for pregnancy.

Avoidance of hyperplastic endometrial states resulting from unopposed estrogen and management of abnormal uterine bleeding in anovulatory episodes can be accomplished with the use of combined hormonal contraceptives. The progestational component inhibits endometrial proliferation and the schedule of pill administration predictably regulates menstrual bleeding. The estrogenic component of combined oral contraceptive elevates circulating sex hormone-binding globulin, which reduces free and bioavailable testosterone levels. Both of the hormonal elements in oral contraceptives combine to suppress gonadotropic (particularly LH) stimulation of ovarian androgen production. DHEAS levels, often contributory to hyperandrogenemia in PCOS, are usually decreased by combined contraceptive use. Products with less-androgenic progestational components (drospirenone, desogestrel) may provide better relief from androgenic symptoms.

Using a product that is well tolerated in long-term use is more important than using a product with particular progestational component. Products with reduced frequency and duration of pill-free intervals can provide superior androgen suppression and a welcome decrease in frequency of bleeding episodes. Depot medroxyprogesterone acetate for contraception, endometrial protection, and androgen suppression may be a suitable alternative to combined hormonal contraceptives; it provides even more profound suppression of ovarian androgen production, but it does not elevate sex hormone-binding globulin. Low-dose progestin-only regimens (oral minipills, implantable progestational contraceptives, and progestin-releasing intrauterine devices) also provide effective endometrial protection but would be expected to provide only partial and/or inconsistent androgen suppression, would not elevate sex hormone-binding globulin, and have not been shown to be consistently helpful in regard to abnormal bleeding patterns.

Patients without the need for management of hyperandrogenic symptoms or contraception are often treated with periodic use of oral progestins to induce predictable menstrual bleeding and prevent endometrial hyperplasia and malignancy. Twelve-day courses of medroxyprogesterone acetate 10 mg daily or norethindrone acetate 5 mg daily are effective and safe for this purpose when taken every 1-2 mo.

Metformin

Metformin is a biguanide medication used to treat type 2 diabetes, its only FDA-approved indication. It has been used in a variety of settings and with differing objectives for patients with PCOS. Metformin exerts its principal effect by reducing hepatic production of glucose and limiting intestinal absorption of glucose. Studies show that a subset of women with PCOS resume regular ovulation and menses when treated with metformin, obviating the need for progestational therapy or ovulation-induction medications to protect endometrial health. For some patients the resulting normal reproductive function is appealing regardless of interest in fertility.

Metformin reduces insulin resistance and the levels of androgens. Its extended use can reduce the likelihood of development of impaired glucose tolerance or the progression of impaired glucose tolerance to type 2 diabetes; these effects are not yet proved for patients with PCOS. It should not be used in the presence of renal or hepatic impairment. Typical dosing is 1,500-2,000 mg/day, achieved through gradual increments because gastrointestinal intolerance is common. Long-acting preparations are helpful when gastrointestinal intolerance is a problem.

The use of metformin in the treatment of PCOS depends on the patient's goals and preference. For the treatment of hyperandrogenic symptoms, metformin effects may be modest compared to other available agents. There are no empiric data supporting the theoretical benefits of long-term use of metformin in adolescents with PCOS and obesity compared to the outcomes achieved with weight loss and oral contraceptive medications. Use of metformin as a first-line agent is favored by some experts, in part for improvement in serum measures of intermediate outcomes, and in part because of evidence in other populations of reduced progression of insulin resistance. There is no evidence for long-term benefit to clinical outcomes of adding metformin to treatment for women managed primarily with oral contraceptives. For adolescents receiving metformin as a first-line medication, progestational management (combined contraceptives or periodic progestins) will still be necessary for those not resuming ovulatory function and oral contraceptives may still be an important adjunct for management of clinical hyperandrogenism and/or contraception.

Antiandrogens

Antiandrogenic medications may be added to other therapies or used alone for the treatment of hirsutism. These agents are usually used integrally or adjunctively with ovarian hormonal suppression, in part because of better reduction in hirsutism when antiandrogens are combined with ovarian suppression but also to reduce the risk of unintended embryonic or fetal exposure. The highly active androgen antagonist and progestin, cyproterone, is available in Europe and in Canada as a single agent for treatment of hirsutism or in combination with ethinyl estradiol as an oral contraceptive with enhanced antiandrogenic profile. In the United States, spironolactone is the most commonly used antiandrogen. Spironolactone antagonizes androgens at their receptor and also impairs androgen synthesis. Doses of 100-200 mg daily are commonly used. Other agents that have been studied are finasteride, a 5α-reductase inhibitor, and flutamide, a nonsteroidal and highly specific androgen receptor antagonist. These are

rarely used because of lack of evidence of superior effectiveness, cost, and, in the case of flutamide, the potential for hepatotoxicity.

HIRSUTISM

Hirsutism is defined as abnormally increased terminal (mature, heavy, dark) hair growth in areas of the body where hair growth is normally androgen dependent (see Chapter 662). Its presence is a result of the combination of extent of androgenic stimulation and familial regional follicle sensitivity to androgens, which varies considerably among ethnic groups. Patients' cosmetic concerns generally determine whether findings of hirsutism are a matter for clinical investigation and treatment. Hirsutism as an isolated finding is to be distinguished from masculinization. The latter includes alteration in muscle mass, clitoral enlargement, and voice change, generally manifesting as a rapid evolution (over months). Masculinization mandates a search for neoplastic source of androgen. Elevations of testosterone or DHEAS commonly indicate an ovarian or adrenal androgen source, respectively; specific imaging and occasionally selective catheterization studies are indicated.

Hirsutism without masculinization is common. The potential causes to consider are PCOS (when there is hyperandrogenism and anovulation), benign functional androgen excess (measurable hyperandrogenism without anovulation), idiopathic hirsutism (increased hair in androgen-dependent areas without measurable androgen excess), and adult-onset adrenal hyperplasia (Table 552-4). Patients can be primarily distinguished by evidence of ovulatory disorder by menstrual history, and for those with absent or irregular menses, a diagnosis of PCOS can be made. The remainder, for whom adult-onset adrenal hyperplasia and PCOS have been excluded, either have normal androgen levels with enhanced end-organ sensitivity owing to familial or ethnic predisposition or have a functional and benign overproduction of ovarian androgens. Measures of androgens (testosterone, DHEAS) may be normal or mildly elevated in the latter group. Testosterone suppresses circulating sex-steroid binding globulin, so states of testosterone overproduction might not be accompanied by elevated measures of total testosterone, although estimates of "free" or "bioavailable" testosterone reveal hyperandrogenism. Measures of unbound testosterone distinguish idiopathic hirsutism from mild benign hyperandrogenic states; making this distinction contributes little to patient management and adds cost. Idiopathic hirsutism (without evidence of androgen excess) usually responds to antiandrogen or androgen suppression therapy similarly to hirsutism associated with elevated androgens and anovulation (PCOS), and benign hyperandrogenism not associated with PCOS.

If hirsutism is present, and clinical evaluation excludes neoplasm, adult-onset adrenal hyperplasia, and Cushing syndrome, then management for symptoms for hyperandrogenism (regardless of whether measures of circulating androgens are elevated or not) can proceed as for patients with PCOS. Estrogen and progestin suppression of ovarian function, with or without added antiandrogen treatment, is the mainstay of therapy for these patients. Androgen suppression and/or antagonism results in gradual regression of the size and productivity of follicles in androgen-sensitive areas of the face and body, and these changes will evolve over successive and months-long generations of hair growth and shedding. Patients should therefore be advised that the effects of medical therapy accrue slowly, over many months.

Chapter 553

Neoplasms and Adolescent Screening for Human Papillomavirus

Nora T. MacZura and Diane F. Merritt

GYNECOLOGIC MALIGNANCIES

After injuries, cancer is the second most common cause of death in adolescents. Although rare, gynecologic malignancies can be followed by infertility, depression, and poor self-image, which may be lifelong.

The most common type of gynecologic malignancy found in children and adolescents is of ovarian origin and usually manifests as an abdominal mass, which must be distinguished from other organ-based tumors and ovarian functional, physiologic, inflammatory/infectious, or pregnancy-related processes. Ovarian neoplasms constitute 1% of all childhood malignancies, but account for 60-70% of all gynecologic malignancies in this age group. Approximately 10-30% of all childhood or adolescent ovarian neoplasms are malignant. Less often, the vagina or cervix is a site of malignant lesions in children, with a few specific tumors having their greatest incidence within this population. Cervical dysplasia can occur in adolescents, and healthcare providers need to be aware of current screening guidelines as well as updates on preventive measures. Vulvar malignancies in children and adolescents are exceedingly rare.

IMPACT OF CANCER THERAPY ON FERTILITY

Chemotherapy and radiation therapy are associated with acute ovarian failure and premature menopause (Table 553-1). Risk factors include

older age, abdominal or spinal radiation, and certain chemotherapeutic drugs, such as alkylating agents (cyclophosphamide, busulfan). Uterine irradiation is associated with infertility, spontaneous pregnancy loss, and intrauterine growth restriction. Decreased uterine volume has been noted in girls who received abdominal radiation. The vagina, bladder, ureters, urethra, and rectum can also be injured by radiation. Vaginal shortening, vaginal stenosis, urinary tract fistulas, and diarrhea are important side effects of pelvic irradiation for pelvic cancers. Pregnancy outcomes appear to be influenced by prior chemotherapy and radiation treatment; 15% of childhood cancer survivors have infertility. Cancer survivors have an increased rate of spontaneous abortions, premature deliveries, and low birthweight infants compared to their normal healthy siblings. No data support an increased incidence of congenital malformations in offspring.

Childhood cancer survivors require extensive counseling about these specific future health implications. As part of informed consent

Table 553-1 Effect of Cancer Treatment on Development of Amenorrhea

	CANCER TREATMENT PROTOCOL	PATIENT AND DOSE FACTORS	COMMON USAGE	FERTILITY PLANNING CONSIDERATIONS
High Risk	Any alkylating agent (e.g., busulfan, carmustine, cyclophosphamide, ifosfamide, lomustine, melphalan, procarbazine) + total body irradiation		Conditioning for HSCT for leukemias, lymphomas, myelomas, Ewing's sarcoma, neuroblastoma, choriocarcinoma	>70% of women develop amenorrhea after treatment. Any treatments containing high doses of alkylating agents and/or radiation to the abdomen, pelvis, or hypothalamic axis present the highest level of risk for gonadal impact and immediate amenorrhea. Patients should be counseled about fertility preservation before treatment.
	Any alkylating agent + pelvic radiation		Sarcomas, ovarian	
	Total cyclophosphamide	5 g/m^2 in women age >40 7.5 g/m^2 in women and girls age <20	Multiple cancers: breast cancer, NHL, conditioning for HSCT	
	Protocols containing procarbazine: MOPP BEACOPP	>3 cycles >6 cycles	Hodgkin lymphoma	
Intermediate Risk	Protocols containing temozolomide or BCNU + cranial radiation		Brain tumor	~30-70% of women develop amenorrhea post-treatment. Lower levels of alkylating agents and/or radiation to the abdomen, pelvis or hypothalamic axis reduce risk of immediate amenorrhea but do not eliminate risk of gonadal damage. Patients should be counseled about fertility preservation prior to treatment. For Bevacizumab, risk of amenorrhea is intermediate, yet the outcome of fertility is unknown.
	Whole abdominal or pelvic radiation doses	>6 Gy in adult women >10 Gy in postpubertal girls >15 Gy in prepubertal girls	Wilms' tumor, neuroblastoma, sarcomas, Hodgkin lymphoma, ovarian	
	Total body irradiation (TBI) doses		HSCT	
	Cranial radiation	>40 Gy	Brain tumor	
	Total cyclophosphamide	5 g/m^2 in women age 30-40	Multiple cancers, breast	
	AC for breast cancer	×4 + paclitaxel or Docetaxel in women age <40	Breast	
	Monoclonal antibodies, e.g., bevacizumab (Avastin)		Colon, non-small cell lung, head and neck, breast	
	FOLFOX$_4$		Colon	
	Protocols containing cisplatin		Cervical	
	Abdominal/pelvic radiation	10-15 Gy in prepubertal girls 5-10 Gy in postpubertal girls	Wilms' tumor, neuroblastoma, spinal tumors, brain tumor, relapsed ALL or NHL	
Lower Risk	Protocols containing nonalkylating agents or lower levels of alkylating agents (e.g., ABVD, CHOP, COP; multi-agent therapies for leukemia)		Hodgkin lymphoma, NHL, leukemia	<30% of women develop amenorrhea after treatment. These treatments are unlikely to cause immediate amenorrhea at standard dosage; however, patients should be counseled that they may be at risk for early menopause. Patients may want to consider fertility preservation before or after treatment.
	Protocols for breast cancer containing cyclophosphamide (e.g., CMF, CEF, or CAF)	Women < 30	Breast	
	Anthracycline + cytarabine		AML	
Very Low / No Risk	Multi-agent therapies using vincristine		Leukemia, lymphoma, breast and lung cancer	
	Radioactive iodine		Thyroid	
Unknown	Monoclonal antibodies, e.g., cetuximab (Erbitux), trastuzumab (Herceptin)		Colon, non-small cell lung, head and neck, breast	Negligible to no effects on menses. Patients should be counseled regarding the lack of conclusive data about the reproductive effects of these drugs; fertility preservation options should be discussed.
	Tyrosine kinase inhibitors, e.g., erlotinib (Tarceva), imatinib (Gleevec)		Non-small cell lung, pancreatic, CML, GIST	

Reproduced with permission from Fertility Risks for Women © LIVESTRONG, a registered trademark of the LIVESTRONG Foundation. http://www.livestrong.org/we-can-help/fertility-services/.

for cancer therapy, the possibility of infertility should be discussed with young patients and their families. Counseling and embryo or mature oocyte cryopreservation for postpubertal females before gonadotoxic therapy should be offered as standard of care. Cryopreservation of ovarian tissue for prepubertal children remains experimental and may be offered as part of a research protocol. Premature ovarian insufficiency is associated with an increased risk for cardiovascular complications, osteoporosis, and difficulties with sexual function. Risks and benefits of hormonal therapy need to be addressed.

OVARIES

Neonatal and Pediatric Ovarian Cysts

Normal follicles or physiologic ovarian cysts are seen by ultrasound examination of the ovaries in all healthy prepubertal girls. Most of these are <1 cm in diameter and not pathologic. In the neonatal period, physiologic follicular cysts as a result of maternal estrogen stimulation usually resolve spontaneously and may be followed with serial ultrasounds in the asymptomatic child. Children with an ovarian mass might have no symptoms and the mass may be detected incidentally or during a routine examination. Other children present with abdominal pain that may be accompanied by nausea, vomiting, or urinary frequency or retention. The cyst's most common complication, **ovarian torsion**, can result in loss of the ovary (autoamputation of the ovary has been documented to occur antenatally). Successful reports of antenatal aspiration and postnatal laparoscopic treatment exist. Large cysts (>4-5 cm), those with complex characteristics, or any ovarian cyst in premenarchal girls with associated signs or symptoms of hormonal stimulation deserve prompt evaluation. The incidence of ovarian cysts increases again with puberty.

Functional Cysts

Hemorrhagic cysts are an expected part of follicular development during the menstrual cycle. Normally, a dominant follicle forms and increases in size. Following ovulation, the dominant follicle becomes a corpus luteum that, if it bleeds, is termed a *hemorrhagic corpus luteum.* These can become symptomatic owing to size or peritoneal irritation from blood, and they have a characteristic complex appearance on ultrasound. Expectant management for a presumed functional or hemorrhagic cyst is appropriate. Physiologic cysts are usually ≤5 cm and resolve over the course of 6-8 wk during subsequent ultrasound imaging. Monophasic oral contraceptives can be used to suppress follicular development to prevent formation of additional cysts.

Teratomas

The most common neoplasm in adolescents is the *mature cystic teratoma (dermoid cyst*). Most are benign and contain mature tissue of ectodermal (skin, hair, sebaceous glands), mesodermal, or endodermal origin. Occasionally, well-formed teeth, cartilage, and bone are found. Calcification on an abdominal radiograph is often a hallmark of a benign teratoma. These tumors may be asymptomatic and found incidentally, or they can manifest as a mass or with abdominal pain (associated with torsion or rupture). If the major component of the dermoid is thyroid tissue (struma ovarii), hyperthyroidism can be the clinical presentation. Benign teratomas should be carefully resected, preserving as much normal ovarian tissue as possible. Oophorectomy (and salpingo-oophorectomy) for this benign lesion is excessive treatment. During surgery, both ovaries should be evaluated, and if there is any question about the nature of the lesion, the specimen should be evaluated by a pathologist. An association of dermoid tumors with neural elements and *anti*–N-*methyl*-D-*aspartase receptor encephalitis* has been reported. Excision of the ovarian tumor has led to improvement in neurologic symptoms in some patients.

Immature teratoma of the ovary is an uncommon tumor, accounting for <1% of ovarian teratomas. In contrast to the mature cystic teratoma, which is encountered most often during the reproductive years but occurs at all ages, the immature teratoma has a specific age incidence, occurring most commonly in the 1st 2 decades of life. By definition, an immature teratoma contains immature neural elements. Because the lesion is rarely bilateral in its ovarian involvement, the present method of therapy consists of unilateral salpingo-oophorectomy with wide sampling of peritoneal implants.

Cystadenomas

Serous and mucinous cystadenomas are the second most common benign ovarian tumor. These cystic lesions can become very large, yet with care, the tumor can be resected, preserving normal ovarian tissue for future reproductive potential.

Endometriomas

Endometriosis is a syndrome defined by the presence of ectopic endometrial tissue usually located within the pelvis and abdomen. The principal clinical symptoms in adolescents consist of severe menstrual pain and pelvic pain. Endometriomas (chocolate cysts) form when the ovaries are involved and are collections of old blood and hemosiderin within an endometrium-lined cyst. They have a typical homogeneous echogenic appearance on ultrasound and are more common in adults than in adolescents. Conservative management (suppressive therapy with ovulation suppression, and nonsteroidal antiinflammatory drugs) and ovarian cystectomy with preservation of as much functioning ovary as possible is recommended for adolescents.

Pelvic Inflammatory Disease and Tuboovarian Abscess

Pelvic inflammatory disease complicated by a tuboovarian abscess should be considered in a sexually active adolescent with an adnexal mass and pain on examination (see Chapter 120). These patients also typically exhibit fever with leukocytosis and cervical motion tenderness. Treatment consists of administration of intravenous antibiotics. If the lesion persists or is refractory to antibiotics, drainage of the pelvic abscess by interventional radiology should be considered.

Adnexal Torsion

Adnexal torsion of the ovary and/or fallopian tube can occur in children or adolescents with normal adnexa or more often those enlarged by cystic (follicular, tubal) changes or ovarian (teratoma, cystadenoma) neoplasms. When torsion occurs, the venous outflow is obstructed first, and the ovary swells and becomes hemorrhagic. Once the arterial flow is interrupted, necrosis begins. It is not known how long torsed adnexa will remain viable. When a female patient presents with acute lower abdominal pain, either episodic or constant, and if imaging studies shows unilateral enlargement of an adnexa, the diagnosis of adnexal torsion must be considered and acted upon. The sonographic presence of Doppler flow does not exclude the diagnosis of torsion. Prompt surgical intervention (laparoscopic detorsion) is warranted if clinical suspicion is high. Detorsion of the adnexa and observation for viability is recommended, with excision only for obviously nonviable necrotic tissues. Recovery of ovarian function after detorsion has been reported with identification of normal follicle development. Oophoropexy (plication) of the affected and the contralateral adnexa remains controversial.

Ovarian Carcinoma

Ovarian cancer is very uncommon in children; only 2% of all ovarian cancers are diagnosed in patients younger than 25 yr old. The Surveillance, Epidemiology, and End Results (SEER) incidence rates are ≤0.8/100,000 at age 0-14 yr and 1.5/100,000 at ages 15-19 yr. Germ cell tumors are the most common and originate from primordial germ cells that then develop into a number of heterogeneous tumor types including dysgerminomas, malignant teratomas, endodermal sinus tumors, embryonal carcinomas, mixed cell neoplasms, and gonadoblastomas. Immature teratomas and endodermal sinus tumors are more aggressive malignancies than dysgerminomas and occur in a significantly higher proportion of younger girls (younger than 10 yr of age). Sex-cord stromal tumors are more common among adolescents (Table 553-2). Tumor markers such as α-fetoprotein, carcinoembryonic antigen, and the antigen CA-125 are also used for diagnosis and treatment surveillance (Table 553-3).

Table 553-2 Malignant Ovarian Tumors in Children and Adolescents

TUMOR	OVERALL 5-YR SURVIVAL	CLINICAL FEATURES
GERM CELL TUMORS		
Dysgerminoma	85%	10-20% bilateral Most common ovarian malignancy Gonadal dysgenesis/androgen insensitivity Sensitive to chemotherapy/radiation
Immature teratoma	97-100%	All 3 germ layers present
Endodermal sinus tumor	80%	Almost always large (>15 cm) Schiller-Duval bodies
Choriocarcinoma	30%	Rare Can mimic ectopic pregnancy
Embryonal carcinoma	25%	Endocrinologic symptoms (precocious puberty) Highly malignant
Gonadoblastoma	100%	Primary amenorrhea Virilization 45,X or 45,X/46,XY mosaicism
SEX CORD STROMAL TUMORS		
Juvenile granulosa stroma cell tumor	92%	Produce estrogen Menstrual irregularities Isosexual precious pseudopuberty Call-Exner bodies rare
Sertoli-Leydig cell tumor	70-90%	Virilization in 40% Produce testosterone
Lipoid cell tumors	~80%	Rare heterogenous group with lipid-filled parenchyma
Gynandroblastoma	90% or greater	Rare low-grade mixed tumors that produce either estrogen or androgen

Table 553-3 Serum Tumor Markers

TUMOR	CA-125	AFP	hCG	LDH	E2	T	INHIBIN	MIS	VEGF	DHEA
Epithelial tumor	+									
Immature teratoma	+	+			+					+
Dysgerminoma			+	+	+					
Endodermal sinus tumor		+								
Embryonal carcinoma		+	+		+					
Choriocarcinoma			+							
Mixed germ cell		+	+	+						
Granulosa cell tumor	+				+		+	+		
Sertoli-Leydig						+	+			
Gonadoblastoma					+	+	+			+
Theca-fibroma									+	

AFP, α-fetoprotein; CA-125, cancer antigen 125; DHEA, dehydroepiandrostenedione; E2, estradiol; hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase; T, testosterone, MIS, müllerian inhibiting substance; VEGF, vascular endothelial growth factor.

Treatment is surgical excision followed by postoperative chemotherapy that usually consists of bleomycin, etoposide, and cisplatin. Radiotherapy is sometimes administered for disease recurrence in dysgerminomas, but it is otherwise not included in routine treatment. Staging at the beginning of therapy is of the utmost importance. In rare cases, a second-look laparotomy may be indicated for neoplasms with teratomatous elements or for those incompletely resected.

Epithelial ovarian cancers account for 19% of ovarian masses in the pediatric population, with a total of 16% being malignant. These tumors manifest almost exclusively after puberty. Common presenting symptoms include dysmenorrhea, abdominal pain, abdominal distention, nausea and vomiting, and vaginal discharge. Tumors of low malignant potential are common in adolescents and account for 30% of epithelial ovarian cancers in this age group. Given the young age of this population, although not the standard of care for adult patients, consideration may be given to conserving the contralateral ovary and uterus if they appear normal. Data suggest that in patients with early-stage disease, such an approach with appropriate surgical staging results in optimal outcomes. Overall 5 yr survival rates are approximately 73%. The number of term pregnancies and use of oral contraceptives decrease the risk of invasive epithelial ovarian cancer. Young women with a family history of ovarian cancer should seriously consider using long-term oral contraceptives for the preventive benefits when pregnancy is not being sought.

UTERUS

Rhabdomyosarcomas are the most common type of soft-tissue sarcoma occurring in patients younger than 20 yr of age (see Chapter 500). They can develop in any organ or tissue within the body except bone, and roughly 3% originate from the uterus or vagina. Of the various histologic subtypes, embryonal rhabdomyosarcomas in the female patient most often occur in the genital tract of infants or young children. They are rapidly growing entities that can cause the tumor to be expelled through the cervix, with subsequent complications such as uterine inversion or large cervical polyps. Irregular vaginal bleeding may be another presenting clinical symptom. They are defined histologically by the presence of mesenchymal cells of skeletal muscle in various stages of differentiation intermixed with myxoid stroma.

Treatment recommendations are based on protocols coordinated by the Intergroup Rhabdomyosarcoma Study Group and consist of a multimodal approach including radiation therapy and chemotherapy. Vincristine, Adriamycin, and cyclophosphamide with or without radiation therapy are the first line of treatment. Resection rates are now very low; chemotherapy with restrictive surgery has enabled many patients to retain their uterus while achieving excellent long-term survival rates.

Leiomyosarcomas and **leiomyomas** are extremely rare, occurring in <2 in 10 million individuals within the pediatric/adolescent age group, although their numbers are increasing among pediatric patients with AIDS. They usually involve the spleen, lung, or gastrointestinal tract, but they could also originate from uterine smooth muscle. Pathogenesis is thought to correlate with the Epstein-Barr virus (see Chapter 254). Despite treatment that demands complete surgical resection (and chemotherapy for the sarcomas), they tend to recur frequently.

Endometrial stromal sarcoma and endometrial adenocarcinoma of the uterine corpus are extremely rare in children and adolescents, with only case reports noted in the literature. Vaginal bleeding not associated with sexual precocity is a common presenting sign. Treatment consists of hysterectomy, with removal of the ovaries, followed by adjunctive radiotherapy and/or chemotherapy, depending on the operative findings.

VAGINA

Sarcoma botryoides is a variant of embryonal rhabdomyosarcoma that occurs most commonly in the vagina of pediatric patients. Sarcoma botryoides tends to arise in the anterior wall of the vagina and manifests as a submucosal lesion that is grape-like in appearance; if located at the cervix it could resemble a cervical polyp or polypoid mass. These lesions were formerly treated with exenterative procedures; equal success has occurred with less-radical surgery (polypectomy, conization, and local excision) and adjuvant chemotherapy with or without radiotherapy. A combination of vincristine, dactinomycin, and cyclophosphamide appears to be effective. Outcomes depend on tumor size, extent of disease at time of diagnosis, and histologic subtype. The 5-year survival rates for patients with clinical stages I-IV were 83%, 70%, 52%, and 25%, respectively.

Vaginal adenosis can lead to the development of clear cell adenocarcinoma of the vagina in females exposed to diethylstilbestrol in utero. Pregnant women at risk for miscarriage are no longer exposed to diethylstilbestrol, and thus fewer adolescent girls and young women are at risk for this unusual tumor.

A rare tumor occurring in the vagina of infants is the **endodermal sinus tumor**. This disease usually occurs in children younger than 2 yr of age, and survival rates are poor. Combination surgery and chemotherapy are appropriate. Benign papillomas can arise in the vagina of children and result in vaginal bleeding. Rarely, vaginal bleeding is secondary to leukemia or a hemangioma.

VULVA

Any questionable vulvar lesion should be biopsied and submitted for histologic examination. Lipoma, liposarcoma, and malignant melanoma of the vulva have been reported in young patients. The most common lesion is likely condyloma acuminata, associated with the human papilloma virus (HPV) (see Chapter 266). Diagnosis is usually made by visual inspection. Treatment consists of observation for spontaneous regression, topical trichloroacetic acid, local cryotherapy, electrocautery, excision, and laser ablation. Some products used to treat skin lesions in adults have not been approved for children, including provider application of podophyllin resin and home application of imiquimod, podofilox, and sinecatechins ointment.

CERVIX

Cervical cancer screening has been cytology based using the Papanicolaou (Pap) test and Bethesda Classification System (Table 553-4). Advances in epidemiologic research and molecular techniques have allowed the identification of the integral role of HPV in development of cervical cancer. HPV has become an important factor in the interpretation of cytologic results and subsequent management. The discovery of HPV presents a unique target for cervical cancer prevention, with the pediatric and adolescent population at the forefront of its implementation. Two HPV vaccines (bivalent HPV2 and quadrivalent HPV4) are currently available to protect against cervical cancer, and the HPV4 vaccine also protects against genital warts and cancers of the anus, vagina, and vulva. HPV vaccines offer the best protection if all three vaccine doses are administered before the patient is ever sexually active. The American Congress of Obstetrics and Gynecology recommends vaccination for all girls and women ages 9-26 yr, and The Advi-

Table 553-4 Management of Cytologic Abnormalities in Adolescents Who Are Screened in Error and Immunocompromised Women <21 Years of Age

CYTOLOGY RESULT	MANAGEMENT RECOMMENDATION	HPV TESTING?	COLPOSCOPY?
ASCUS	Repeat cytologic testing in 1 year	No	At 1 yr follow-up if HGSIL or greater result At 2 yr follow-up if persistent ASCUS or greater
LGSIL	Repeat cytologic testing in 1 year	No	At 1 yr follow-up if HGSIL or greater result At 2 yr follow-up if ASCUS or greater
HGSIL	If colposcopy is unsatisfactory or if CIN is ungraded: excisional procedure If colposcopy is satisfactory: • If no CIN1-3: Pap and colposcopy q6mo until 2 are negative. **If persistent HGSIL without CIN1-3 identified, then excisional procedure at 2 yr** • If CIN1: (ASCUS/LGSIL protocol) • If CIN2, CIN2-3: Pap or colposcopy q6mo until 2 are negative, or else rebiopsy at 1 yr, treat if persistent at 2 yr • If CIN3: excisional procedure	No	Yes, immediately
ASC-H or AGC	There are no specific recommendations in regard to adolescents; see ASCCP guidelines for adults Endometrial biopsy is not advised in adolescents	No	Yes, immediately

Note: Cryotherapy and laser ablation are acceptable treatment options only for biopsy-proven CIN2+ lesion and satisfactory colposcopic examination.
AGC, atypical glandular cells; ASCCP, American Society for Colposcopy and Cervical Pathology; ASC-H, atypical squamous cell changes, high grade; ASCUS, atypical squamous cell changes of undetermined significance; CIN, cervical dysplasia; HGSIL, high-grade squamous intraepithelial dysplasia; LGSIL, low-grade squamous intraepithelial dysplasia; Pap, Papanicolaou smear.

sory Committee on Immunization Practices (http://www.cdc.gov/vaccines/schedules/hcp/index.html) recommends routine vaccination of girls ages 11-12 yr with 3 doses of quadrivalent HPV vaccine, starting as early as age 9 yr. Catch-up vaccination is indicated for girls and women ages 13-26 yr who have not been fully vaccinated. Female patients should be vaccinated even if sexually exposed; vaccination prior to exposure is ideal. Pap testing and screening for HPV DNA or HPV antibody is not required before vaccination. The American Congress of Obstetrics and Gynecology recommends that cervical cancer screening of women who have been immunized against HPV-16 and HPV-18 should not differ from that of nonimmunized women and should follow the exact same regimen.

The adolescent population presents a unique challenge to cervical cancer screening, because the prevalence of HPV is high. In adolescents ages 15-19 yr, HPV cumulative incidence rates after initiation of sexual activity are reported as 17% at 1 yr and 35.7% at 3 yr. Correlating with the natural history of an HPV infection, >90% of low-grade intraepithelial lesions regress within this age group, giving the presence of HPV in this population little clinical significance. The overall incidence of a high-grade lesion on Pap test in the adolescent population remains low (0.7%); cervical cancer is uncommon in the age group. In the United States, the Surveillance, Epidemiology, and End Results Cancer Statistics Review 1975-2006 published by the National Cancer Institute reports an incidence of invasive cervical cancer as 0.1/100,000 in 15-19 yr olds, with no cases reported before the age of 15 yr; similar rates (≤0.3 cases per 100,000 among women ages 15-19 yr) have been reported by the Canadian Cancer Registry. Therefore, colposcopy for minor cytologic abnormalities within this age group should be highly discouraged, because it will result more often in harm than produce any clinical benefit. The American Society for Colposcopy and Cervical Pathology and the American College of Obstetricians and Gynecologists guidelines recommend that adolescents should be managed conservatively and should not receive Pap smear screening until age 21 yr regardless of age of onset of sexual intercourse. If an HPV test is done, the results should be ignored. However, sexually active immunocompromised (HIV-positive patients or organ transplant recipients) adolescents should undergo screening twice within the 1st yr after diagnosis and annually thereafter. Table 553-4 demonstrates management recommendations for abnormal cytologic results for adolescents who are screened in error and immunocompromised sexually active adolescents who are screened. Routine screening for cervical cancer in the general adolescent population (younger than age 21 yr) is *not* recommended.

Clinic protocols that require teenagers to undergo Pap smears before prescribing contraceptives should be reconsidered in light of these recommendations.

Chapter 554
Vulvovaginal and Müllerian Anomalies

Natalia M. Grindler and Amber R. Cooper

EMBRYOLOGY

Cellular differentiation, duct elongation, fusion, resorption, canalization, and programmed cell death are all involved in the sequence of events that occur in a developing embryo and early fetus to create a normal reproductive system. Myriad gonadal, müllerian, and/or vulvovaginal anomalies can result from interruption of the intricate sequence or functions of any one of these processes during formation of the reproductive system (Table 554-1). Genetic, epigenetic, enzymatic, and environmental factors all have some role in the process (Table 554-2).

Table 554-1 Common Müllerian Anomalies

ANOMALY	DESCRIPTION
Hydrocolpos	Accumulation of mucus or nonsanguineous fluid in the vagina
Hemihematometra	Atretic segment of vagina with menstrual fluid accumulation
Hydrosalpinx	Accumulation of serous fluid in the fallopian tube, often an end result of pyosalpinx
Didelphic uterus	Two cervices, each associated with 1 uterine horn
Bicornuate uterus	One cervix associated with 2 uterine horns
Unicornuate uterus	Result of failure of 1 müllerian duct to descend

Phenotypic sexual differentiation, especially during formation of the vulvovaginal and müllerian systems, is determined from genetic (46,XX), gonadal, and hormonal influences (see Chapter 582). The genetic sex of the embryo is determined at fertilization when the gamete pronuclei fuse. The primordial germ cells (oogonia or spermatogonia) migrate from the yolk sac to the gonadal ridges. The primitive gonads are indistinguishable until about the 7th wk of development. Gonadal development determines the progression or regression of the genital ducts and subsequent hormonal production and, thus, the external genitalia. Critical areas in the SRY region (sex-determining region on the Y chromosome) are believed to be the factors that drive the development of a testis from a primitive gonad as well as spermatogenesis. The testis begins to develop between 6 and 7 wk of gestation, first with Sertoli cells followed by Leydig cells, and testosterone production begins at approximately 8 wk of gestation. The genital tract begins to differentiate later than the gonads. The differentiation of the wolffian ducts begins with an increase in testosterone, and the local action of testosterone activates development of the epididymis, vas deferens, and seminal vesicle. Further male genital duct and external genital structures depend on the conversion of testosterone to dihydrotestosterone.

In a 46,XX embryo, female sexual differentiation occurs about 2 wk later than gonadal differentiation in the male. Because the ovaries develop prior to and separately from the müllerian ducts, females with müllerian ductal anomalies usually have normal ovaries and steroid hormone production. The regression of the wolffian ducts results from the lack of local gonadal testosterone production, and the persistence of the **müllerian** (or paramesonephric) **ducts** results from the absence of **antimüllerian hormone** (or müllerian-inhibiting substance) production. The müllerian ducts continue to differentiate into the fallopian tubes, uterus, and upper vagina without interference from antimüllerian hormone. There are complex interactions among the mesonephric, paramesonephric, and metanephric ducts early in embryonic development, and normal development of the müllerian system depends on such interaction. If this process is interrupted, coexisting müllerian and renal anomalies are often discovered in the female patient at the time of evaluation. Differentiation along the female pathway is often referred to as the *default pathway,* but it is an extremely intricate process regulated by the absence, presence, or dosage compensation of numerous gene products (i.e., SRY, SF-1, WTI, SOX9, Wnt-4, GATA4, DAX-1, BMP4, HOX genes) and remains not entirely understood.

By 10 wk of gestation, the caudal portions of the müllerian ducts fuse together in the midline to form the uterus, cervix, and upper vagina, in a Y-shaped structure, with the open upper arms of the Y forming the primordial fallopian tubes. Initially the müllerian ducts are solid cords that gradually canalize as they grow along and cross

the mesonephric ducts ventrally and fuse in the midline. The mesonephric ducts caudally open into the **urogenital sinus**, and the müllerian ducts contact the dorsal wall of the urogenital sinus, where proliferation of the cells at the point of contact form the müllerian tubercle. Cells between the müllerian tubercle and the urogenital sinus continue to proliferate, forming the vaginal plate. At the same time of the midline fusion of the müllerian ducts, the medial walls begin to degenerate and resorption occurs to form the central cavity of the uterovaginal canal. Uterine septal resorption is thought to occur in a caudal to cephalad direction and to be complete at approximately 20 wk of gestation. This theory has been scrutinized because some anomalies do not fit the standard classification system. It is possible that septal resorption starts at some point in the middle and proceeds in both directions. At approximately 16 wk of gestation the central cells of the vaginal plate desquamate and resorption occurs, forming the vaginal lumen. The lumen of the vagina is initially separated from the urogenital sinus by a thin hymenal membrane. The hymenal membrane undergoes apoptosis and central resorption and is usually perforate before birth.

EPIDEMIOLOGY

Müllerian anomalies can include abnormalities in portions or all of the fallopian tubes, uterus, cervix, and vagina (Fig. 554-1). True estimates of prevalence are difficult because of the varied presentations and asymptomatic nature of some of the anomalies. Imaging techniques have made significant contributions to uterovaginal anomaly diagnoses, which has increased reporting of anomalies and led to additional combinations of anomalies. Most estimate that müllerian anomalies are present in 2-4% of the female population. The incidence increases in women with a history of adverse pregnancy outcomes or infertility: 5-10% of infertile women undergoing hysterosalpingogram, 5-10% of women with recurrent pregnancy loss, and 25% or more of women with late miscarriages and/or preterm delivery have müllerian defects.

CLINICAL MANIFESTATIONS

Vulvovaginal and müllerian anomalies can manifest at a variety of chronological time points during a female's life: from infancy, through childhood and adolescence, and adulthood (see Table 554-1). The majority of external genitalia malformations manifest at birth, and often even subtle deviations from normal in either a male or female newborn warrant evaluation. Structural reproductive tract abnormalities can be seen at birth or can cluster at menarche or any time during a woman's reproductive life. Some müllerian anomalies are asymptomatic, whereas others can cause gynecologic, obstetric, or infertility issues.

Clinical manifestations and treatments depend on the specific type of müllerian anomaly and are varied. There may be a pelvic mass, which may or may not be associated with symptoms. A mass bulging at the introitus or within the vagina indicates complete or partial

Table 554-2 Heritable Disorders Associated with Müllerian Anomalies

MODE OF INHERITANCE	DISORDER	ASSOCIATED MÜLLERIAN DEFECT
Autosomal dominant	Camptobrachydactyly Hand-foot-genital	Longitudinal vaginal septa Incomplete müllerian fusion
Autosomal recessive	McKusick-Kaufman Johanson-Blizzard Renal-genital-middle ear anomalies Fraser syndrome Uterine hernia syndrome	Transverse vaginal septa Longitudinal vaginal septa Vaginal atresia Incomplete müllerian fusion Persistent müllerian duct derivatives
Polygenic/multifactorial	Mayer-Rokitansky-Küster-Hauser syndrome	Müllerian aplasia
X-linked	Uterine hernia syndrome	Persistent müllerian duct derivatives

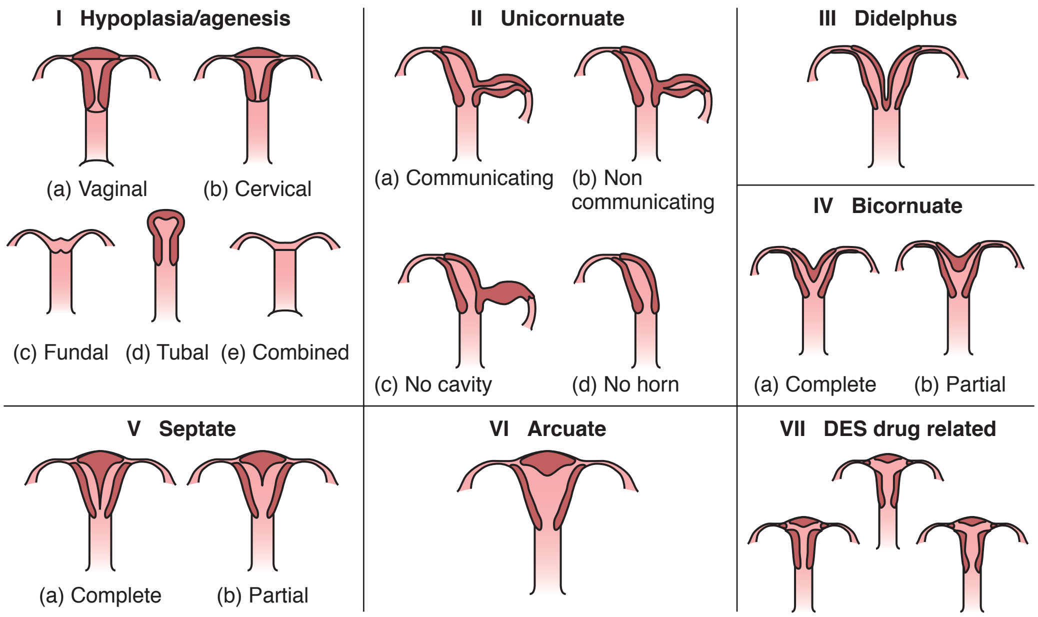

Figure 554-1 Classification system of müllerian duct anomalies developed by the American Fertility Society. *(From Gholoum S, Puligandla PS, Hui T, et al: Management and outcome of patients with combined vaginal septum, bifid uterus, and ipsilateral renal agenesis [Herlyn-Werner-Wunderlich syndrome].* J Pediatr Surg *41:987–992, 2006, Fig. 3.)*

outflow tract obstruction. An adolescent can present with pelvic pain either in association with primary amenorrhea or several months after the onset of menarche. Patients also may be asymptomatic until they present with miscarriage, pregnancy loss, or preterm delivery. When presentation is acutely symptomatic, emergency management may be required. Obstruction can result from a number of distinct anomalies including an **imperforate hymen**, **transverse vaginal septum**, and **noncommunicating rudimentary horn**. As menstrual fluid accumulates proximal to the obstruction, the resulting **hematocolpos** and **hematometra** cause cyclic pain or a pelvic mass.

Prenatal or neonatal presentation of hydrometrocolpos from distal vaginal obstruction produces fluid accumulation in the vagina and uterus and presents as a lower abdominal mass with or without associated acute urinary tract obstruction. **Hydrometrocolpos with polydactyly** may be a result of 2 disorders: McKusick-Kaufman syndrome (with associated congenital heart disease) and Bardet-Biedl syndrome (with obesity, learning disabilities, retinitis pigmentosa, renal anomalies). Both are autosomal recessive disorders.

Adolescent patients can present with acute obstruction of the outflow tract because of a müllerian anomaly, which requires emergency evaluation and surgical treatment. A small percentage of girls present with concomitant urinary retention caused by an altered urethral angle or pressure on the sacral plexus. Urinary hesitancy and incomplete emptying symptoms may be present before abdominopelvic pain from the obstruction in a patient of any age.

LABORATORY FINDINGS

Several radiographic studies have been used, often in combination, to aid in diagnosis including ultrasound, hysterosalpingogram, sonohysterography (saline-infusion sonography), and MRI. Laparoscopy and hysteroscopy were the gold standard for evaluation of müllerian anomalies, but the new standard may be MRI because of its noninvasive, high-quality capabilities. MRI is the most sensitive and specific imaging technique used for evaluating müllerian anomalies because it can image nearly all reproductive structures, blood flow, external contours, junctional zone resolution on T2-weighted images, and associated renal and other anomalies. MRI also has a high correlation with surgical findings because of its multiplanar capabilities and high spatial resolution. Three-dimensional ultrasound is another useful diagnostic tool and may be superior to traditional pelvic ultrasound and hysterosalpingogram. Three-dimensional ultrasound and MRI results are highly concordant in the diagnosis of uterine malformations. Evaluation of the external contour of the uterus is important for differentiating types of uterine anomalies. This often requires a combination of radiologic modalities for uterine cavity, external contour, and possible tubal patency. Diagnostic laparoscopy or hysteroscopy may be necessary depending on the presentation, but it is used less with the advancement of MRI and other imaging.

Diagnosis of müllerian anomalies should include a physical exam, pelvic ultrasound, possibly MRI, and renal and skeletal inspections for associated anomalies. Renal anomalies are noted in 30-40% and skeletal anomalies are associated in 10-15% of patients with müllerian anomalies. Unilateral renal agenesis occurs in 15% of patients. The most common skeletal anomalies are vertebral. Patients usually have a normal female karyotype (46,XX), but several familial segregations and gene mutations and/or abnormal karyotypes have been reported (see Table 554-2). Approximately 5-8% of patients with congenital müllerian anomalies have abnormal karyotypes. Most malformations are sporadic, with a polygenic mechanism and multifactorial etiology.

UTERINE ANOMALIES

Anomalous development of the uterus may be symmetric or asymmetric and/or obstructed or nonobstructed. Patients can present with primary amenorrhea or have either irregular or regular menstrual cycles. There may be an asymptomatic pelvic mass or dysmenorrhea. In adolescents and adults, pregnancy loss can cause the first suspicion of a uterine anomaly. Treatment is highly specific to the specific anomaly.

SEPTATE UTERUS

A **uterine septum** is the most common of all müllerian anomalies, accounting for just over half of all abnormalities, and it is the most common structural uterine anomaly. After the 2 müllerian ducts fuse in the midline, resorption must occur to unify the endometrial cavities; failure of this process results in some degree of uterine septum. It can vary in length from just below the fundus to beyond the cervix, depending on the amount of caudal resorption. A **septate uterus** has a normal external uterine contour, which is what distinguishes it from a bicornuate or didelphic uterus. An MRI can help delineate between a predominantly fibrous septum and a muscular or myometrial septum. Because the septum may be poorly vascularized, a septate uterus is the most significant anomaly associated with pregnancy loss, as well as other untoward pregnancy outcomes. Hysteroscopic metroplasty (septal excision) is generally recommended in the setting of a previous pregnancy loss. Controversy still exists regarding whether a woman should have such a surgical procedure without a previous pregnancy loss. Correction of uterine septum improves the prognosis in patients with a history of adverse obstetrical outcomes (i.e., spontaneous abortions, preterm delivery). The length of the septum might not correlate with the frequency or occurrence of untoward pregnancy outcomes. Differentiating precisely between bicornuate and septate uteri is extremely important to determine effective and safe treatment plans.

Bicornuate Uterus

Both müllerian ducts develop and elongate in this anomaly, but they do not completely fuse in the midline. The vagina and external cervix are normal, but the extent of division of the 2 endometrial cavities can vary depending on the extent of failed fusion between the cervix and the fundus. Bicornuate uteri are also associated with increased preterm labor and delivery, malpresentation, and miscarriage. This anomaly accounts for approximately 10-20% of müllerian anomalies and a significant percentage of uterine anomalies.

Unicornuate Uterus and Rudimentary Horns

A **unicornuate uterus** results from a normal creation of a fallopian tube, functional uterus, cervix and vagina from 1 müllerian duct. The other side fails to develop, resulting in either absence of the contralateral müllerian duct or a rudimentary horn. There is a 30-40% association of renal anomalies. If a rudimentary horn is identified, it is important to determine whether functional endometrium is present (usually with T2-weighted MRI images). About two-thirds of rudimentary horns are noncommunicating, some with a fibrous band connecting the 2 structures. Rudimentary horns can also communicate with the contralateral uterus. A fertilized ovum can implant and develop within a rudimentary horn. These pregnancies are incompatible with expectant gestation, and rupture of the horn could be life-threatening. Rupture tends to occur at a later gestation than with an ectopic pregnancy, and hemorrhage is severe. Patients with rudimentary horns with functioning endometrium can also present with pain caused by accumulating menses. Because the other horn has a normal outflow pathway, these patients present with pain, not primary amenorrhea. Pregnancies that arise in a unicornuate uterus are associated with increased preterm labor and delivery, malpresentation, and miscarriage.

Uterine Didelphys

A **uterine didelphys** is the result a complete failure of fusion and represents 5% of müllerian anomalies. There are 2 fallopian tubes, 2 completely separate uterine cavities, 2 cervices, and often 2 vaginal canals or 2 partial canals because of an associated longitudinal vaginal septum (75% of the time). Evaluation for renal anomalies should be pursued because they are common as well. At times, the longitudinal septum attaches to 1 sidewall and obstructs 1 side of the vagina (or hemivagina). The combination of uterine didelphys, obstructed hemivagina, and ipsilateral renal agenesis is a variant of the broad spectrum of müllerian anomalies that is referred to as the **Heryln-Werner-Wunderlich syndrome** or **obstructed hemivagina and ipsilateral**

renal anomaly syndrome in the literature. Adolescents with this disorder usually present with abdominal pain shortly after menarche. Although there still may be a risk of adverse pregnancy outcomes with a uterine didelphys (preterm labor, malpresentation), overall pregnancy outcomes are generally good and are associated with less risk than in other uterine anomalies.

Arcuate Uterus

An **arcuate uterus** is a uterine cavity that has a small midline septum, from lack of a small amount of resorption, and sometimes a slight indentation of the uterine fundus. An arcuate uterus might represent a variant of normal rather than a müllerian anomaly. Untoward pregnancy outcomes are rare and surgical correction is not warranted.

Uterine Anomalies in Diethylstilbestrol-Exposed Patients

Intrauterine diethylstilbestrol (DES) exposure is associated with an increased risk for development of uterine anomalies and clear cell adenocarcinoma of the vagina and cervix. DES was used to prevent preterm delivery, but this practice was discontinued in 1971. Commonly observed uterine features associated with DES exposure include the following: T-shaped uterus, cervical hypoplasia, fallopian tube irregularities, scalloped or irregularly shaped endometrial contour, constriction bands, and others. DES suppresses and/or alters *Wnt* and *HOX* genes in mice and thus might work by affecting gene expression in müllerian duct development, causing uterine abnormalities, vaginal adenosis, and potentially carcinoma.

Treatment

Treatment depends on the specific anomaly. Hysteroscopic surgical resection is widely supported for uterine septa. If a septate uterus extends through the cervical canal, many choose to leave this cervical portion of the septum because of concerns for future incompetence, although case reports indicate that incisions have been done with uneventful follow-up. Most would support the incision of a uterine septum in the clinical setting of pregnancy loss, but some would also support prophylactic metroplasty without a history of miscarriage, especially before in vitro fertilization.

A noncommunicating horn with functional endometrium should be resected to improve quality of life or prevent future complications; opinions vary as to whether resection of a communicating horn or one with no functional endometrium is warranted. Any surgical resection of a rudimentary horn requires careful surgical technique to protect the ipsilateral ovarian blood supply and the myometrium of the remaining unicornuate uterus.

Although metroplasty had been advocated with didelphic and bicornuate uteri and a history of poor pregnancy outcomes in the past, currently most clinicians feel there is not enough evidence to support such a complicated procedure. Any obstruction to the outflow tract must also be relieved; this can necessitate creation of a vaginal window or excision of a hemivaginal septum.

VAGINAL ANOMALIES

Abnormalities of the Hymen

An **imperforate hymen** is the most common obstructive anomaly, and familial occurrences have been reported. Its incidence is most often reported as approximately 1 in 1,000. In the newborn period and early infancy, it may be diagnosed by a bulging membrane caused by a mucocolpos from maternal estrogen stimulation of the vaginal mucosa. This can eventually reabsorb if it is not too large or symptomatic. More often it is diagnosed at the time of menarche, when menstrual fluid accumulates. The clinical manifestations often are a bulging blue-black membrane, pain, primary amenorrhea, and normal secondary sex characters. Depending on the circumstance, patients might have cyclic abdominal pain or a pelvic mass. Other hymenal abnormalities have been reported. A normal hymen can have various configurations (annular, crescentic). Some hymenal membranes do not undergo complete resorption or perforation, resulting in microperforate, cribriform, or septate-shaped hymen. Infants and children vary in age as to when these are recognized, but hymenal anomalies are often discovered after menarche when it is difficult for an adolescent to place a tampon, so resection is indicated.

Congenital Absence of the Vagina and Mayer-Rokitansky-Küster-Hauser Syndrome

Vaginal agenesis or **atresia** results when the vaginal plate fails to canalize. On physical exam it appears as an extremely foreshortened vagina, sometimes referred to as a *vaginal dimple*. Isolated (partial) vaginal agenesis involves an area of aplasia between the distal vaginal portion and a normal upper vagina, cervix, and uterus. On initial presentation it may be confused with a low transverse septum or imperforate hymen, and therefore clear delineation of the anomaly is critical before attempting surgical repair. It can also manifest with cyclic pain and a bulging mass just after menarche. Surgical repair and reconstruction are complicated and individualized and best performed with consultation of specialists.

Uterine and vaginal agenesis often occur together because of their close association during development, when müllerian ductal development fails early in the process. The most common cause of vaginal agenesis is **Mayer-Rokitansky-Küster-Hauser syndrome**, with an incidence reported at 1 in 4,000-10,000 female births. After gonadal dysgenesis, müllerian agenesis is the second most common cause of primary amenorrhea. The cause is unknown and likely has a multigenetic and multifactorial etiology. Mayer-Rokitansky-Küster-Hauser syndrome is characterized by primary amenorrhea, normal vulva, anomalies of the uterus (usually aplasia or agenesis), attenuated fallopian tubes, normal ovaries, normal female karyotype and phenotype, and associated anomalies (most commonly renal and skeletal). The vagina either is completely absent or only has a small dimpled opening. Although most patients with müllerian agenesis have small rudimentary müllerian bulbs, approximately 2-7% of patients can have active endometrium within these uterine structures. These patients will often present with cyclic pelvic pain. MRI imaging is often necessary to determine if any small uterine remnant is present (often located on the pelvic sidewall or near the ovaries and only a small fibromuscular remnant) and to clearly delineate the anomaly. Laparoscopy is not necessary to diagnosis müllerian agenesis but may be useful in the treatment of rudimentary uterine horns, particularly when removal of obstructed uterine structures or associated endometriosis is indicated for pelvic pain. Absence of the vagina and uterus has significant anatomic, physiologic, and psychologic implications for the patient and family. Any diagnosis of müllerian agenesis must be differentiated from androgen insensitivity (testicular feminization) as well; karyotype, serum testosterone levels, and pubic hair distribution usually help distinguish between the two.

Lesions involving other organ systems occur in association with the Mayer-Rokitansky-Küster-Hauser syndrome. The most common are urinary tract anomalies (15-40%) primarily involving unilateral absence of a kidney, a horseshoe or pelvic kidney, and skeletal anomalies (5-10%), which primarily involve vertebral development but can also include hearing impairment.

Longitudinal Vaginal Septa

Longitudinal vaginal septa represent failure of complete canalization of the vagina. These often occur in the presence of uterine anomalies as noted earlier.

Transverse Vaginal Septa (Vertical Fusion Defects)

Vertical fusion defects can result in a transverse septum, which may be imperforate and associated with hematocolpos or hematometra in adolescents or with mucocolpos in infants. These are much less common anomalies, reportedly found in 1 in 80,000 females. Most patients present with amenorrhea and cyclical pain around the time of menarche. Patients who have a small opening in the transverse septa might present with prolonged vaginal drainage and discharge. Transverse vaginal septa vary in location in the vagina (15-20% in the lower third, but most in the middle or upper third of the vagina) and thickness but

are generally ≤1 cm thick. High locations, thick septa, and narrow vaginal orifices present challenging surgical cases.

Transverse vaginal septa may be associated with other congenital anomalies, although this occurs less often than with müllerian agenesis. These patients have a functional normal uterus, unlike women with Mayer-Rokitansky-Küster-Hauser syndrome. There is also an increased incidence of endometriosis secondary to retrograde menstruation.

Evaluation of transverse vaginal septa includes careful pelvic examination and often pelvic imaging, usually with MRI and ultrasound, to delineate the anatomic abnormalities. MRI is especially helpful to determine the thickness of the septum and presence of a cervix and for surgical planning. Diagnosis and treatment plans should be made as soon as possible after menarche, because significant accumulation of hematometra and/or hematosalpinx could affect future reproductive success by negatively affecting uterine and/or tubal function.

Treatment

An imperforate hymen requires resection to prevent or relieve the outflow tract obstruction. Many approach it with a horizontal, lunate or cruciate incision, excision of excess tissue, and reanastomosis of the mucosal edges. Repair should be done at time of diagnosis, if the patient is symptomatic. Although the lesion may be repaired any time during infancy, childhood, or adolescence, surgery is facilitated by estrogen stimulation and thus is ideally performed in adolescence, either after puberty or menarche. Variants in the hymen with microperforations or hymenal septa may interfere with tampon use and resection of this tissue is usually electively performed.

Treatment of congenital absence of the vagina is usually delayed until the patient is ready to be sexually active. The nonsurgical approach is the most common first-line therapy owing to the high success rate and extremely low morbidity. It requires dedicated use of dilators to create a functional vagina. The series of dilators come in progressively increasing sizes and require a commitment and maturity on the part of the patient to comply with daily use (20-30 min daily). If done correctly it is possible to achieve a functional vaginal length (6-8 cm), width, and physiologic angle for intercourse in about 6-8 wk of therapy. When the ultimate size that accommodates coitus is reached, then the patient must use the dilator or have coitus with a frequency that maintains adequate length.

Surgical approaches require more expertise and often some postoperative vaginal dilation to ensure a functional result. Controversy exists among surgical subspecialties, because pediatric surgeons and pediatric urologists often recommend creating the neovagina in infancy. Pediatric gynecologists and reproductive endocrinologists believe better outcomes result from creating the neovagina when the young woman is interested in sexual activity and can participate in the decision to have surgery and in her own postoperative recovery. There is no consensus as to the best surgical option; the most-used procedures include 2 surgical approaches followed by dilators or an approach using a loop of bowel out of which to construct a vagina. Patients need to be counseled about the ability to use their own oocytes and a gestational carrier through in vitro fertilization to achieve pregnancy. These therapies can be quite complicated physically and emotionally. They are best approached in a multidisciplinary fashion, often with the assistance of psychologic counseling and surgeons with specialized training.

For transverse vaginal septa, treatment is surgical resection of the obstruction through a vaginal approach. Some surgeons advocate waiting for 1 or more menstrual cycles or using preoperative dilators from below to increase the depth and circumference of the distal vagina and to allow menstrual blood to accumulate and dilate the upper portion of the vagina. Complete resection of the septum, with primary anastomosis of the upper and lower mucosal segments, should be attempted. A vaginal stent is sometimes placed postoperatively in the vagina to maintain patency and allow squamous epithelization of the upper vagina and cervix. Follow-up dilation may be necessary after the stent is removed. Careful preoperative assessment is important because surgeons who begin a case believing they are operating on an imperforate hymen can find themselves in entirely different and more complex surgical planes. Regardless of the approach, vaginoplasty is often best deferred until the patient is mature and physically and psychologically prepared to participate in the healing process and postoperative dilator treatments.

Longitudinal vaginal septa themselves do not lead to adverse reproductive outcomes but may be symptomatic in a patient, causing dyspareunia, difficulties with tampon insertion, or impedance during vaginal birth. Such complaints can warrant a resection of the vaginal septa. In a small number of patients there may be unilateral obstruction of a hemivagina, which would require incision and resection.

CERVICAL ANOMALIES

Congenital atresia or complete agenesis of the uterine cervix is extremely rare and often manifests at puberty with amenorrhea and pelvic pain. It is associated with significant renal anomalies in 5-10% of patients. A pelvic MRI is often warranted to completely define the abnormality. Usually, pain and obstruction are significant and a hysterectomy is necessary. Attempts to reconnect the uterus to the vagina are rarely successful and associated with significant morbidity and reoperation rates. As with most müllerian anomalies, the ovaries usually remain normal and future reproduction can still occur through the use of in vitro fertilization and a gestational carrier.

VULVAR AND OTHER ANOMALIES

Complete Vulvar Duplication

Duplication of the vulva is a rare congenital anomaly that is seen in infancy and consists of 2 vulvas, 2 vaginas, and 2 bladders, a didelphic uterus, a single rectum and anus, and 2 renal systems.

Labial Asymmetry and Hypertrophy

With the onset of puberty the labia minora enlarge and grow to an adult size. A woman's labia can vary in size and shape. Asymmetry of the labia, where the right and left labia are different in size and appearance, is a normal variant. Some women are uncomfortable with what they perceive to be their asymmetric or enlarged labia minora and complain about self-consciousness and discomfort while wearing tight clothing, exercising, or having sex. The enlarged labia can have a protuberant and abnormal appearance that can be functionally or psychologically bothersome. Local irritation, problems of personal hygiene with bowel movements or menses, interference with sexual intercourse or while sitting or exercising have resulted in requests for labial reduction. Some surgeons are advertising procedures to reduce uneven or enlarged labia minora. The American College of Obstetricians and Gynecologists does not support performing such surgery unless there is significant impairment in function. Medically indicated surgical procedures can include reversal or repair of female genital cutting and treatment for labial hypertrophy or asymmetrical labial growth secondary to congenital conditions, chronic irritation, or excessive androgenic hormones. Complications of labial surgery include loss of sensation, keloid formation, and dyspareunia.

Clitoral Abnormalities

Agenesis of the clitoris is rare. Clitoral duplication has been reported, often associated with pelvic organ abnormalities, including agenesis of other genital tract structures and bladder exstrophy. Exposure to male hormones will result in clitoral enlargement, and is often a sign of a testosterone producing tumor or use of exogenous steroids.

Cloacal Anomalies

Cloacal anomalies are rare lesions representing a common urogenital sinus into which the gastrointestinal, urinary, and vaginal canals all exit. Usually there is an abnormality in all or some of the processes of fusion of the müllerian ducts, development of the sinovaginal bulbs, or development of the vaginal plate. The single opening (cloaca) requires surgical correction, preferably by a multidisciplinary pediatric surgical team.

Ductal Remnants

Even though the opposite duct regresses in both sexes, there can sometimes be a small portion of either the müllerian or wolffian duct that

remains in either the male or female, respectively. Such remnants can form cysts, which is what makes them clinically visible during surgery, examination, or imaging. Most do not cause pain, although torsion of some has been reported, and small asymptomatic ones usually do not require resection. The most commonly reported are hydatid of Morgagni cysts (remnant of a wolffian duct arising from the fallopian tube), cysts of the broad ligament, and Gartner's duct cysts, which can form an ectopic ureter or be found along the cervix or vaginal walls.

Chapter 555

Gynecologic Care for Girls with Special Needs

Elisabeth H. Quint

Adolescence presents challenges for all children and their families, but particularly so for teens with special needs and their families. The start of menstrual periods, the mood changes associated with puberty and the concerns about sexual activity with possible unplanned pregnancies, and worries about safety and abuse may present teens with disabilities and their families with additional issues.

SEXUALITY AND SEXUAL EDUCATION

Adolescents with special needs can have physical and/or developmental disabilities. These young women are often seen as asexual by their families, care providers, and society and therefore sexual education might not have been provided or considered necessary. Physically disabled teens are as likely to be sexually active as nondisabled teens. The care provider needs to assess the teen's knowledge of anatomy and sexuality, her social knowledge of relationships, and her ability to consent to sexual activity. Education regarding HIV and other sexually transmitted infections, disease prevention, and contraception, including postcoital contraception, should be offered at a developmentally appropriate level. Teens with disabilities may be more at risk for isolation and depression during adolescence.

ABUSE

The risk for sexual abuse in teens with disabilities is difficult to estimate. Screening for abuse is mandatory. Studies show that teens with physical disabilities are just as sexually active as their nondisabled counterparts but that more of their activity is nonvoluntary. Patients with cognitive impairment are often taught to be cooperative, which may make them more vulnerable. Abuse prevention education can include the No! Go! Tell! model. For teens with limited verbal capacity or developmental delay, abuse may be very hard to detect. The care provider needs to be vigilant in looking for signs on physical exam, such as unexplained bruises or scratches, or changes in behavior, such as regression, which may be indications of sexual abuse in those adolescents (see Chapters 40.1 and 119).

PELVIC EXAMINATION

An internal pelvic exam is rarely indicated in teens that are not sexually active, as Papanicolaou smears are not recommended to start until age 21 yr. An external genital exam can be performed, if there are vulvar issues such as discharge, irregular bleeding, suspicion for abuse, or foreign body. The frogleg position is usually favored over the use of stirrups. If the vagina or cervix needs to be clearly visualized for a medical indication, an exam under anesthesia by a gynecologist should be considered. Testing for sexually transmitted infections can be accomplished by urine testing or vaginal swabs (see Chapter 120).

MENSTRUATION

Irregular menstruation is common in teenagers, especially during the 1st 5 yr after menarche, because of immaturity of the hypothalamic–pituitary–ovarian axis and subsequent anovulation (see Chapter 116). Several conditions in teens with disabilities are associated with an even higher risk of irregular cycles. Teens with Down syndrome have a higher incidence of thyroid disease. There is a higher incidence of reproductive issues, including polycystic ovarian syndrome in teens with epilepsy and on certain antiepileptic drugs (see Chapter 552). Antipsychotic medication can cause hyperprolactinemia, which can affect menstruation.

For teens with disabilities the main issue with menstrual cycles, whether they are regular, irregular, or heavy, is the impact of menstruation on the patient's life, her health, and her ability to perform her normal activities. The history should focus on this aspect, and menstrual calendars may be helpful to document the cycles, behavior, and the impact of treatments. Most adolescents who self-toilet can learn to use menstrual hygiene products appropriately.

The evaluation for abnormal bleeding is the same as for all teens. Areas requiring particular attention for the girl with special needs are the consideration of menstrual suppression for hygiene or cyclical behavioral issues, like crying, tantrums, or withdrawal. A request for birth control, especially coming from a caregiver and not from the teen, requires an evaluation of the teen's ability to consent to sexual activity and evaluate the safety of her environment. Guidelines for abnormal bleeding include menses that are too heavy (in excess of 1 pad/hr for several hours in a row), too long (longer than 10 days), or too frequent (fewer than 20 days apart).

Treatment of Menstruation

If after documenting the impact of the regular or irregular cycles on the patient's well-being (often through menstrual or behavioral charting for several months), the care provider, patient, and family decide on menstrual intervention, several options are available. Menstrual regulation is not different from that in the nondisabled teenager in general, although there are some special considerations. Goals for treatment can be to decrease the heaviness of flow, regulate cycles to predictable bleeding, relieve pain or cyclical behavior symptoms, provide contraception, and/or obtain amenorrhea. Menstrual suppression leading to complete amenorrhea is usually difficult to obtain and infrequent scheduled bleeds may be easier to manage than unpredictable spotting, a common side effect of any suppressive treatment, for certain patients. After treatment has started, continue to monitor cycles, ideally with continued menstrual or behavior calendars.

Nonhormonal Methods

If menorrhagia or dysmenorrhea (occasionally leading to cyclical behavior changes in nonverbal teens) is the main concern, the patient can be started on nonsteroidal antiinflammatory drugs. These can decrease the flow by up to 20% in adequate doses and can be used alone or in combination with other treatments.

Estrogen-Containing Methods

Oral Contraceptives

Cyclical oral contraceptives usually lead to regular, lighter cycles with less cramping. Extended cycling through the use of continuous use of oral contraceptives can suppress cycles, with amenorrhea rates improving with time. Some unpredictable spotting is usually unavoidable, and often teens with special needs prefer to have predictable cycles several times a year. A chewable oral contraceptive is available for those with swallowing issues.

Contraceptive Ring

The contraceptive ring is usually used in a pattern of 3 wk on and 1 wk off, but it can be used (off-label) in a continuous 4-wk pattern, which can lead to less bleeding. However, the contraceptive ring may be difficult to use for a teen with dexterity problems and help with placement has obvious privacy issues.

Contraceptive Patch

The weekly patch can also be used in a continuous fashion. Some teens with developmental disabilities remove their patch erratically, and placement out of reach (e.g., on buttocks or shoulder) is advised.

Estrogen Use, Venous Thromboembolism and Mobility Issues

Immobility per se is not a contraindication to estrogen-containing contraceptives, according to the Centers for Disease Control and Prevention medical eligibility criteria for contraception released in 2010. There are some data to support the concern that higher-dose oral estrogen, the combined estrogen patch, and the newer progestin preparations may have a higher risk for venous thromboembolism. However, there are minimal data on the risk of venous thromboembolism in teens with mobility issues in wheelchairs with or without extraneous estrogen. It is important to obtain a thorough and extended family history for hypercoagulability before initiating estrogen therapy. Careful use of lower-dose (30 or 20 µg) ethinyl estradiol preparations may be advisable and third-generation progestin combinations and the patch should only be used if other methods have failed.

Progestin-Only Methods

Intramuscular Medroxyprogesterone Acetate

Intramuscular medroxyprogesterone acetate (DMPA) has long been used for menstrual suppression. Two issues are particularly relevant to teens with disabilities. Studies documenting a decrease in bone density associated with longer-term use of DMPA and a black box warning by the FDA have raised concerns about use of these products in young women, although research indicates that the bone density improves after the medication is stopped. For teens with mobility issues or those with very low body weight who are already at risk for low bone density, decreased bone density is a real concern, although the risk of fractures is unclear. Adequate calcium and vitamin D is recommended. The second issue for teens with mobility issues is weight gain associated with DMPA, especially among obese teens, which can lead to transfer and mobility issues. If long-term DMPA is considered for a specific patient, calcium and vitamin D supplementation is recommended and bone density could be measured after several years of use, and weight should be monitored closely.

Oral Progestins

Continuous oral progestins can also be very effective to obtain amenorrhea. The progesterone-only minipill causes significant irregular spotting, so if full suppression is the goal, then other progestins can be used daily, such as norethindrone 2.5 or 5 mg or micronized progesterone 200 mg.

Progesterone Intrauterine Device

The 5 yr levonorgestrel-intrauterine device has now been used for many teenagers for contraception as well as heavy menses. Teens with special needs might require anesthesia for insertion if the exam is very difficult because of discomfort, contractures, or a narrow vagina. Checking for strings in a clinic setting may be challenging; however, the intrauterine device location can be confirmed by sonography. There may be a significant amount of irregular bleeding and spotting in the 1st several mo, but there is 20% amenorrhea after insertion and up to 50% amenorrhea after 1 year of use. The bleeding profile of the newer and smaller 3 year progesterone intrauterine device may not be as helpful for menstrual suppression as the amenorrhea rates from the initial studies by the manufacturer are 6% at 1 year, but more studies are needed.

Implants

Progestin subdermal implants have relatively low amenorrhea rates and high rates of unscheduled bleeding and therefore might not be ideal for teens with special needs, as they also require significant patient cooperation for insertion.

Hormones and Antiepileptic Drugs

Certain enzyme-inducing seizure medications can interfere with oral contraceptives, change their effectiveness, and/or lead to intermittent bleeding. Higher estrogen dose or shorter injection intervals for DMPA may be considered. The only antiepileptic medication that is affected by combined oral contraceptives is lamotrigine; consequently, the dose of that medication may need to be adjusted if used in conjunction with hormones.

Surgical Methods

Surgical procedures such as endometrial ablation, a procedure where the lining of the uterus is surgically removed, and hysterectomy are available for treatment of abnormal periods in adults, but they should only rarely be used in extreme situations for teenagers where all other methods have failed and the patient's health is severely compromised by her cycles. Endometrial ablation only leads to amenorrhea approximately 30% of the time and has a higher failure rate in women younger than 40 yr of age. Ethical considerations around these methods leading to infertility and consent issues are complicated, and state law varies on this topic.

CONTRACEPTION

See also Chapter 117.

The menstrual manipulation methods discussed above can also be used for contraception and if a request for birth control is made, an evaluation of the patient's ability to consent to sexual activity and the safety of her environment should be done. The method chosen should be the safest method for her situation with the highest protection rate. If she is dependent on others a long-acting reversible contraceptive method may be advisable. Sexually transmitted infections and condom use should be addressed with the teen and specific guidelines on how to obtain condoms and negotiate its use may be needed. A discussion about postcoital contraception is recommended, as well as ways to help the teen obtain this if indicated.

Bibliography is available at Expert Consult.

555.1 Female Genital Mutilation/Cutting

Robert M. Kliegman

Female genital mutilation/cutting (FGM/C) is a common practice in many parts of the world and is considered a form of child abuse and is illegal in most countries. It is estimated that more than 125 million women in 29 countries have undergone FGM/C (Fig. 555-1). FGM/C breaches international human rights laws and is considered a criminal act.

FGM/C has no health benefit. It threatens the health of girls and women having adverse effects on their psychologic, sexual, and reproductive well-being (Table 555-1). In addition, it increases the risk of HIV infection.

CLASSIFICATIONS

Type I: Partial or complete removal of the clitoris, prepuce, or both

Type II: Mutilation or cutting producing partial or complete removal of the clitoris and labia minora with or without excision of the labia majora

Type III: Infibulation; narrowing and sealing of the vaginal orifice by cutting and apposition of the labia minora or majora with or without excision of the clitoris

Type IV: All other harmful procedures

Table 555-1	Health Consequences of Female Genital Mutilation
IMMEDIATE RISKS Pain, shock (caused by pain or hemorrhage, or both), excessive bleeding, difficulty passing urine or feces, infection (including tetanus inoculation and the transmission of bloodborne viruses such as HIV, hepatitis B, and hepatitis C), psychologic consequences (as a result of pain, shock, or physical restraint), unintended labial fusion, death (caused by hemorrhage or infection).	
LONG-TERM RISKS Pain (chronic neuropathic pain), keloid scarring, infections (including chronic pelvic infections, recurrent urinary tract infections, and an increased incidence of certain genital infections), birth complications (cesarean section, postpartum hemorrhage, and episiotomy), danger to the newborn (including death), decreased quality of sexual life, psychologic consequences (including posttraumatic stress disorder, depression, and anxiety)	
LONG-TERM RISKS PARTICULAR TO TYPE 3 FEMALE GENITAL MUTILATION Need for later surgery (deinfibulation), urinary and menstrual problems, painful sexual intercourse, and infertility	

From Simpson J, Robinson K, Creighton SM, Hodes D: Female genital mutilation: the role of health professionals in prevention, assessment, and management. BMJ *344:e1361, 2012, Box 3.*

West African women are at greater risk of type II FGM/C, while those in northeast and east Africa and the Middle East are subjected to type III FGM/C. Nonetheless because of migration, women and girls in the United States and Western Europe may undergo FGM/C by traditional practitioners or, rarely, ethnic minority obstetricians or other physicians. Many ethnic women at risk for FGM/C living in the United States or Western Europe are more ambivalent about the procedure demonstrating a conflict between 2 cultures.

MANAGEMENT

This is a complex ethnic minority issue that often goes undetected until complications develop, either acutely from the procedure or during pregnancy. Criminalization alone will not eliminate this practice because it is performed in secret, and women are reluctant to discuss this with their healthcare provider, but laws against these procedures are an important step in reducing the number of women subjected to FGM/C.

Surgical repair, such as clitoral reconstruction with removal of scar tissue has been quite beneficial in decreasing pain and enhancing pleasure, including orgasm. Furthermore, women report a positive effect on their self-image and female identity as well as a new sense of "completeness" after reconstructive surgery.

The Endocrine System

PART XXVI

Section 1

Disorders of the Hypothalamus and Pituitary Gland

Chapter 556

Hormones of the Hypothalamus and Pituitary

Eric I. Felner and John S. Parks

The pituitary gland is the major regulator of an elaborate hormonal system. The pituitary gland receives signals from the hypothalamus and responds by sending pituitary hormones to target glands. The target glands produce hormones that provide negative feedback at the level of the hypothalamus and pituitary (Fig. 556-1). This feedback mechanism enables the pituitary to regulate the amount of hormone released into the bloodstream by the target glands. The pituitary's central role in this hormonal system and its ability to interpret and respond to a variety of signals have led to its designation as the "master gland." Table 556-1 lists hypothalamic and pituitary hormones and their functions.

ANATOMY

The pituitary gland is located at the base of the skull in a saddle-shaped cavity of the sphenoid bone called the *sella turcica.* The bony structure protects and surrounds the pituitary bilaterally and inferiorly. The dura, a dense layer of connective tissue, forms the roof of the sella. An external layer of the dura continues into the sella to form its lining. As a result, the pituitary is extradural and is not normally in contact with cerebrospinal fluid. The pituitary gland is connected to the hypothalamus by the pituitary stalk. The pituitary gland is composed of an anterior (adenohypophysis) and a posterior (neurohypophysis) lobe. The anterior lobe constitutes approximately 80% of the gland.

EMBRYOLOGY

The anterior pituitary gland originates from the Rathke pouch as an invagination of the oral ectoderm. It then detaches from the oral epithelium and becomes an individual structure of rapidly proliferating cells. By 6 wk of gestation, the connection between the Rathke pouch and the oropharynx is completely obliterated, and the pouch establishes a direct connection with the downward extension of the hypothalamus, which gives rise to the pituitary stalk. Persistent remnants of the original connection between the Rathke pouch and the oral cavity can develop into **craniopharyngiomas** (see Chapter 497), the most common type of tumor in this area.

VASCULAR SUPPLY

The arterial blood supply of the pituitary gland originates from the internal carotid via the inferior, middle, and superior hypophyseal arteries. This network of vessels forms a unique portal circulation connecting the hypothalamus and pituitary. The branches of the superior hypophyseal arteries penetrate the stalk and form a network of vessels that traverse the pituitary stalk and terminate in a network of capillaries within the anterior lobe. It is through this portal venous system that hypothalamic hormones are delivered to the anterior pituitary gland. Anterior pituitary hormones, in turn, are secreted into a secondary plexus of portal veins that drain into the dural venous sinuses.

ANTERIOR PITUITARY CELL TYPES

A series of sequentially expressed transcriptional activation factors directs the differentiation and proliferation of anterior pituitary cell types. These proteins are members of a large family of DNA-binding proteins resembling homeobox genes. The consequences of mutations in several of these genes are evident in human forms of multiple pituitary hormone deficiency. Five cell types in the anterior pituitary produce 6 peptide hormones. Somatotropes produce growth hormone (GH), lactotropes produce prolactin (PRL), thyrotropes make thyroid-stimulating hormone (TSH), corticotropes express proopiomelanocortin, the precursor of adrenocorticotropic hormone (ACTH), and gonadotropes express luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

Growth Hormone

Human GH is a 191-amino-acid single-chain polypeptide that is synthesized, stored, and secreted by somatotropes in the pituitary. Its gene *(GH1)* is the first in a cluster of 5 closely related genes on the long arm of chromosome 17 (q22-24). The 4 other genes *(CS1, CS2, GH2,* and *CSP)* have >90% sequence identity with the *GH1* gene.

GH is secreted in a pulsatile fashion under the regulation of hypothalamic hormones. The alternating secretion of growth hormone–releasing hormone, which stimulates GH release, and somatostatin, which inhibits GH release, accounts for the rhythmic secretion of GH. Peaks of GH occur when peaks of growth hormone–releasing hormone coincide with troughs of somatostatin. **Ghrelin,** a peptide produced in the arcuate nucleus of the hypothalamus and in much greater quantities by the stomach, also stimulates GH secretion. In addition to the 3 hypothalamic hormones, physiologic factors play a role in stimulating and inhibiting GH. Sleep, exercise, physical stress, trauma, acute illness, puberty, fasting, and hypoglycemia stimulate the release of GH whereas hyperglycemia, hypothyroidism, and glucocorticoids inhibit GH release.

GH binds to receptor molecules on the surface of target cells. The GH receptor is a 620-amino-acid, single-chain molecule with an extracellular domain, a single membrane-spanning domain, and a cytoplasmic domain. Proteolytically cleaved fragments of the extracellular domain circulate in plasma and act as a GH-binding protein. As in other members of the cytokine receptor family, the cytoplasmic domain of the GH receptor lacks intrinsic kinase activity; instead, GH binding induces receptor dimerization and activation of a receptor-associated Janus kinase (Jak2). Phosphorylation of the kinase and other protein substrates initiates a series of events that leads to alterations in nuclear gene transcription. The signal transducer and activator of transcription 5b (STAT5b) plays a critical role in linking receptor activation to changes in gene transcription.

The biologic effects of GH include increases in linear growth, bone thickness, soft tissue growth, protein synthesis, fatty acid release from adipose tissue, insulin resistance, and blood glucose. The mitogenic actions of GH are mediated through increases in the synthesis of **insulin-like growth factor** 1 (IGF-1), formerly named *somatomedin C*, a 70-amino-acid single-chain peptide coded for by a gene on the long arm of chromosome 12. IGF-1 has considerable homology to

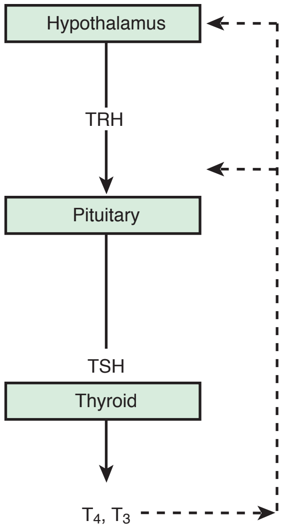

Figure 556-1 Hypothalamic–pituitary–thyroid (HPT) axis. Thyroid-releasing hormone (TRH) from the hypothalamus stimulates the pituitary gland to secrete thyroid-stimulating hormone (TSH). TSH stimulates the thyroid gland to produce and secrete thyroid hormones (T_4 and T_3). High circulating levels of T_3 and T_4 inhibit further TRH and TSH secretion and thyroid hormone production through a negative feedback mechanism *(dashed lines)*. T_3, triiodothyronine; T_4, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone (thyrotropin); <---, inhibits; ←, stimulates.

Table 556-1 Hormones of the Hypothalamus and Pituitary Gland

HORMONES	LOCATION	S/I	FUNCTION
ACTH	Anterior pituitary	S	Production and secretion of GCs, MCs, and androgens from adrenal gland
ADH	Posterior pituitary	S	Reabsorption of water into the bloodstream via renal collecting ducts
CRH	Hypothalamus	S	Secretion of ACTH
Dopamine	Hypothalamus	S	Secretion of PRL
FSH (females)	Anterior pituitary	I	Secretion of estrogen from ovary
FSH (males)	Anterior pituitary	S	Production of sperm from testis
GH	Anterior pituitary	S	Secretion of IGF-1
GHRH	Hypothalamus	S	Secretion of GH
Ghrelin	Hypothalamus	S	Secretion of GH
GnRH	Hypothalamus	S	Secretion of FSH and LH
LH (females)	Anterior pituitary	S	Ovulation and development of the corpus luteum
LH (males)	Anterior pituitary	S	Production and secretion of testosterone
Oxytocin	Posterior pituitary	S	Contractions of uterus at birth and release of milk from breast
PRL	Anterior pituitary	S	Promotion of milk synthesis
Somatostatin	Hypothalamus	I	Secretion of GH and TSH
TRH	Hypothalamus	S	Secretion of TSH and PRL
TSH	Anterior pituitary	S	Secretion of T_4 and T_3

ACTH, adrenocorticotropic hormone; ADH, antidiuretic hormone; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GC, glucocorticoids; GH, growth hormone; GHRH, growth hormone–releasing hormone; GnRH, gonadotropin-releasing hormone; IGF-1, insulin-derived growth factor 1; LH, luteinizing hormone; MC, mineralocorticoids; PRL, prolactin; S/I, stimulate/inhibit; T_3, triiodothyronine; T_4, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone (thyrotropin).

insulin. Circulating IGF-1 is synthesized primarily in the liver and formed locally in mesodermal and ectodermal cells, particularly in the growth plates of children, where its effect is exerted by paracrine or autocrine mechanisms. Circulating levels of IGF-1 are related to blood levels of GH and to nutritional status. IGF-1 circulates bound to several different binding proteins. The major one is a 150-kDa complex (IGF-BP3) that is decreased in GH-deficient children. Human recombinant IGF-1 might have therapeutic potential in conditions characterized by end organ resistance to GH such as Laron syndrome and the development of antibodies to administered GH. IGF-2 is a 67-amino-acid single-chain protein that is coded for by a gene on the short arm of chromosome 11. It has homology to IGF-1. Less is known about its physiologic role, but it appears to be an important mitogen in bone cells, where it occurs in a concentration many times higher than that of IGF-1.

Prolactin

PRL is a 199-amino-acid peptide made in pituitary lactotropes. The regulation of PRL is unique because PRL is consistently secreted unless it is actively inhibited by dopamine, a peptide produced by neurons in the hypothalamus. Disruption of the hypothalamus or pituitary stalk can result in elevated PRL levels. Dopamine antagonists, states of primary hypothyroidism, administration of thyrotropin-releasing hormone (TRH), and pituitary tumors result in increased serum levels of PRL. Dopamine agonists and processes causing destruction of the pituitary cause reduced levels of PRL.

The primary physiologic role for PRL is the initiation and maintenance of lactation. PRL prepares the breasts for lactation and stimulates milk production postpartum. During pregnancy, PRL stimulates the development of the milk-secretory apparatus, but lactation does not occur because of the high levels of estrogen and progesterone. After delivery, the estrogen and progesterone levels drop and physiologic stimuli such as suckling and nipple stimulation signal PRL release and initiate lactation.

Thyroid-Stimulating Hormone

TSH consists of 2 glycoprotein chains (α, β) linked by hydrogen bonding; the α-subunit, which is composed of 89 amino acids and is identical to other glycoproteins (FSH, LH, and human chorionic gonadotropin), and the β-subunit, composed of 112 amino acids, that is specific for TSH.

TSH is stored in secretory granules and released into circulation primarily in response to TRH, which is produced by the hypothalamus. TRH is released from the hypothalamus into the hypothalamic–pituitary portal system and ultimately stimulates TSH release from pituitary thyrotropes. TSH stimulates release of thyroxine (T_4) and triiodothyronine (T_3) from the thyroid gland through the formation of cyclic adenosine monophosphate and the G protein second messenger system. In addition to the negative feedback inhibition by T_3, the release of TRH and TSH is inhibited by dopamine, somatostatin, and glucocorticoids.

Deficiency of TSH results in inactivity and atrophy of the thyroid gland, whereas excess TSH results in hypertrophy and hyperplasia of the thyroid gland.

Adrenocorticotropic Hormone

ACTH is a 39-amino-acid single-chain peptide that is derived by proteolytic cleavage from proopiomelanocortin, a 240-amino-acid

precursor glycoprotein product of the pituitary gland. Proopiomelanocortin also contains the sequences for the lipotropins, melanocyte-stimulating hormones, and β-endorphin.

Secretion of ACTH is regulated by corticotropin-releasing hormone (CRH), a 41-amino-acid peptide found predominantly in the median eminence but also in other areas in and outside of the brain. ACTH is secreted in a diurnal pattern. It acts on the adrenal cortex to stimulate cortisol synthesis and secretion. ACTH and cortisol levels are highest in the morning at the time of waking, are low in the late afternoon and evening, and reach their nadir 1-2 hr after beginning sleep. ACTH also appears to be the principal pigmentary hormone in humans. Similar to TRH and TSH, CRH and ACTH function through the formation of cyclic adenosine monophosphate and the G protein second-messenger system. Although CRH is the primary regulator of ACTH secretion, other hormones play a role. Arginine vasopressin, oxytocin, angiotensin II, and cholecystokinin stimulate release of CRH and ACTH, whereas atrial natriuretic peptide and opioids inhibit release of CRH and ACTH. Similar to the feedback inhibition T_3 has on TRH and TSH, cortisol also inhibits CRH and ACTH. Physiologic conditions, such as stress, fasting, and hypoglycemia, also stimulate release of CRH and ACTH.

Luteinizing Hormone and Follicle-Stimulating Hormone

Gonadotropic hormones include 2 glycoproteins, LH and FSH. They contain the same α subunit as TSH and human chorionic gonadotropin but distinct β subunits. Receptors for FSH on the ovarian granulosa cells and on testicular Sertoli cells mediate FSH stimulation of follicular development in the ovary and of gametogenesis in the testis. On binding to specific receptors on ovarian theca cells and testicular Leydig cells, LH promotes luteinization of the ovary and Leydig cell function of the testis. The receptors for LH and FSH belong to a class of receptors with 7 membrane-spanning protein domains. Receptor occupancy activates adenylyl cyclase through the mediation of G proteins.

Luteinizing hormone–releasing hormone, a decapeptide, has been isolated, synthesized, and widely used in clinical studies. Because it leads to the release of LH and FSH from the same gonadotropic cells, it appears that it is the only gonadotropin-releasing hormone.

Secretion of LH is inhibited by androgens and estrogens, and secretion of FSH is suppressed by gonadal production of inhibin, a 31-kDa glycoprotein produced by the Sertoli cells. Inhibin consists of α and β subunits joined by disulfide bonds. The β-β dimer (activin) also occurs, but its biologic effect is to stimulate FSH secretion. The biologic features of these more recently identified hormones are being delineated. In addition to its endocrine effect, activin has paracrine effects in the testis. It facilitates LH-induced testosterone production, indicating a direct effect of Sertoli cells on Leydig cells.

POSTERIOR PITUITARY CELL TYPES

The posterior lobe of the pituitary is part of a functional unit, the neurohypophysis, that consists of the neurons of the supraoptic and paraventricular nuclei of the hypothalamus; neuronal axons, which form the pituitary stalk; and neuronal terminals in the median eminence or in the posterior lobe. Arginine vasopressin (antidiuretic hormone [ADH]) and oxytocin are the 2 hormones produced by neurosecretion in the hypothalamic nuclei and released from the posterior pituitary. They are octapeptides and differ by only 2 amino acids.

Antidiuretic Hormone

ADH regulates water conservation at the level of the kidney by increasing the permeability of the renal collecting duct to water. ADH stimulates translocation of water channels through its interaction with vasopressin 2 receptors in the collecting duct, which act through G proteins to increase adenylyl cyclase activity and increase permeability to water. V2 receptors also mediate the von Willebrand factor and tissue plasminogen activator. At higher concentrations, ADH activates V1 receptors in smooth muscle cells and hepatocytes and exerts pressor and glycogenolytic effects through mobilization of intracellular calcium stores. Separate V3 receptors mediate stimulation of ACTH secretion. These effects involve phosphatidylinositol hydrolysis rather than cyclic adenosine monophosphate production.

ADH and its accompanying protein neurophysin II are encoded by the same gene. A single preprohormone is cleaved and the 2 are transported to neurosecretory vesicles in the posterior pituitary. The 2 are released in equimolar amounts.

ADH has a short half-life and responds quickly to changes in hydration. The stimuli for its release are increased plasma osmolality, perceived by osmoreceptors in the hypothalamus, and decreased blood volume, perceived by baroreceptors in the carotid sinus of the aortic arch.

Oxytocin

Oxytocin stimulates uterine contractions at the time of labor and delivery in response to distention of the reproductive tract and stimulates smooth muscle contraction in the breast during suckling, which results in milk letdown. Studies suggest that oxytocin also plays a role in orgasm, social recognition, pair bonding, anxiety, trust, love, and maternal behavior. Most recently, through the interaction with its G-protein-coupled receptor in pancreatic and adipose tissue, oxytocin appears to play a significant role in appetite regulation and obesity by inducing anorexia.

Chapter 557

Hypopituitarism

John S. Parks and Eric I. Felner

Hypopituitarism denotes underproduction of growth hormone (GH) alone or in combination with deficiencies of other pituitary hormones. Affected children have postnatal growth impairment that is specifically corrected by replacement of GH. The incidence of congenital hypopituitarism is thought to be between 1 in 4,000 and 1 in 10,000 live births. With expanding knowledge of the genes that direct pituitary development or hormone production, an increasing proportion of cases can be attributed to specific genetic disorders. Mutations in 7 candidate genes account for 13% of isolated growth hormone deficiency (IGHD) and 20% of multiple pituitary hormone deficiency (MPHD) cases. The likelihood of finding mutations is increased by consanguinity and occurrence in siblings or across generations. The genes, hormonal phenotypes, associated abnormalities, and modes of transmission for such established genetic disorders are shown in Tables 557-1 through 557-4. Acquired hypopituitarism usually has a later onset and different causes (Table 557-5).

MULTIPLE PITUITARY HORMONE DEFICIENCY

Genetic Forms

Sequentially expressed transcriptional activation factors direct the differentiation and proliferation of anterior pituitary cell types. These proteins are members of a large family of DNA-binding proteins resembling homeobox genes. Mutations produce different forms of MPHD. *PROP1* and *POU1F1* genes are expressed fairly late in pituitary development only in cells of the anterior pituitary and result in hypopituitarism without anomalies of other organ systems. The *HESX1, LHX3, LHX4,* and *PTX2* genes are expressed at earlier stages and are not restricted to the pituitary. Mutations in these genes tend to produce phenotypes that extend beyond hypopituitarism to include abnormalities in other organs.

Table 557-1 Etiologic Classification of Multiple Pituitary Hormone Deficiency

GENE OR LOCATION	PHENOTYPE	INHERITANCE
GENETIC FORMS		
POU1F1 (PIT1)	GH, TSH, PRL	R, D
PROP1	GH, TSH, PRL, LH, FSH, ±ACTH, variable AP	R
LHX3	GH, TSH, PRL, LH, FSH, variable AP, ±short neck	R
LHX4	GH, TSH, ACTH, small AP, EPP, ±Arnold-Chiari	D
TPIT	ACTH, severe neonatal form	R
HESX1	GH, variable for others, small AP, EPP	R, D
SOX3	Variable deficiencies, ±MR, EPP, small AP and stalk	XL
PTX2	Rieger syndrome	D
GLI2	Holoprosencephaly, midline defects	D
GLI3	Hall-Pallister syndrome	D
SHH (sonic hedgehog)	GH deficiency with single central incisor	D
ACQUIRED FORMS		
Idiopathic		
Irradiation	GH deficiency precedes other deficiencies	
Inflammation	Histiocytosis, sarcoidosis	
Autoimmune	Hypophysitis	
Postsurgical	Stalk section, vascular compromise	
Tumor	Craniopharyngioma, glioma, pinealoma	
Trauma	Battering, shaken baby, vehicular	
UNCERTAIN ETIOLOGY		
Idiopathic		
Congenital absence of pituitary		
Septooptic dysplasia		
Birth trauma		

ACTH, adrenocorticotropic hormone; AP, anterior pituitary; D, dominant; EPP, ectopic posterior pituitary; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; MR, mental retardation; PRL, prolactin; R, recessive; TSH, thyroid-stimulating hormone; XL, X-linked.

PROP1

PROP1 is found in the nuclei of somatotropes, lactotropes, and thyrotropes. Its roles include turning on *POU1F1* expression, hence its name prophet of *PIT1*. Mutations of *PROP1* are the most common explanation for recessive MPHD and are 10 times as common as the combined total of mutations in other pituitary transcription factor genes. Deletions of 1 or 2 base pairs in exon 2 are most common, followed by missense, nonsense, and splice-site mutations. Anterior pituitary hormone deficiencies are seldom evident in the neonatal period. The median age at diagnosis of GH deficiency is around 6 yr. Recognition of thyroid-stimulating hormone (TSH), luteinizing hormone (LH), follicle-stimulating hormone, and adrenocorticotropin (ACTH) deficiencies is delayed relative to recognition of GH deficiency. Anterior pituitary size is small in most patients, but in others there is progressive enlargement of the pituitary.

POU1F1 (PIT1)

POU1F1 (formerly *PIT1*) was identified as a nuclear protein that binds to the GH and prolactin promoters. It is necessary for emergence and mature function of somatotropes, lactotropes, and thyrotropes. Dominant and recessive mutations in *POU1F1* are responsible for

Table 557-2 Established Genetic Defects of the GH-IGF Axis Resulting in IGF Deficiency

MUTANT GENE	INHERITANCE	PHENOTYPE
HPA		Developmental abnormalities
HESX1	AR	Septooptic dysplasia; variable involvement of pituitary hormones
PROP1	AR	GH, PRL, TSH, LH, FSH deficiencies; variable ACTH deficiency
POU1F1 (PIT1)	AR, AD	GH, PRL deficiency; variable degree of TSH deficiency
RIEG	AD	Rieger syndrome
LHX3	AR	GH, TSH, LH, FSH, prolactin deficiencies
LHX4	AD	GH, TSH, ACTH deficiencies
SOX3	XL	GH deficiency, mental retardation
GLI2	AD	Holoprosencephaly, hypopituitarism
GLI3	AD	Pallister-Hall syndrome, hypopituitarism
IGHD		
GHRHR	AR	IGHD, type IB form of IGHD
GHS-R	AD	GHD and ISS
GH1	AR AR AD XL AD	Type IA form of IGHD Type IB form of IGHD Type II form of IGHD Type III form of IGHD; hypogammaglobulinemia Bioinactive GH molecule
GHI		
GHR		
Extracellular domain	AR, AD	IGF-I deficiency; decreased or normal GHBP
Transmembrane	AR	IGF-I deficiency; normal or increased GHBP
Intracellular domain	AD	IGF-I deficiency; normal or increased GHBP
IGF		
IGF1	AR	IGF-1 deficiency; IUGR and postnatal growth failure
STAT5b	AR	IGF-1 deficiency, variable immune defect, hyperprolactinemia, chronic pulmonary infections, recurrent eczema
ALS	AR	IGF-1 deficiency; variable postnatal growth failure, delayed puberty

ACTH, adrenocorticotropic hormone (corticotropin); AD, autosomal dominant; ALS, acid labile subunit; AR, autosomal recessive; FSH, follicle-stimulating hormone; GH, growth hormone; GHBP, GH-binding protein; GHD, growth hormone deficiency; GHRHR, GH-releasing hormone receptor; HPA, hypothalamic pituitary; IGF, insulin-like growth factor; IGHD, isolated GHD; ISS, idiopathic short stature; IUGR, intrauterine growth retardation; LH, luteinizing hormone; PRL, prolactin; TSH, thyroid-stimulating hormone; XL, X-linked.

From David A, Hwa V, Metherell L, et al: Evidence for a continuum of genetic, phenotypic, and biochemical abnormalities in children with growth hormone insensitivity. Endocr Rev *32:472–497, 2011, Table 2.*

Table 557-4 Proposed Classification of Growth Hormone Insensitivity

Primary GH insensitivity (hereditary defects)
- GH receptor defect (may be positive or negative for GH-binding protein)
  - Extracellular mutation (e.g., Laron syndrome)
  - Cytoplasmic mutation
  - Intracellular mutation
- GH signal transduction defects (distal to cytoplasmic domain of GH receptor)
  - Stat5b mutations
- Insulin-like growth factor-1 defects
  - IGF-1 gene deletion
  - IGF-1 transport defect (ALS mutation)
  - IGF-1 receptor defect
- Bioinactive GH molecule (responds to exogenous GH)

Secondary GH insensitivity (acquired defects)
- Circulating antibodies to GH that inhibit GH action
- Antibodies to the GH receptor
- GH insensitivity caused by malnutrition, liver disease, catabolic states, diabetes mellitus
- Other conditions that cause GH insensitivity

GH insensitivity: Clinical and biochemical features of IGF-1 deficiency and insensitivity to exogenous GH, associated with GH secretion that would not be considered abnormally low.

GH insensitivity syndrome: GH insensitivity associated with the recognizable dysmorphic features described by Laron.

Partial GH insensitivity: GH insensitivity in the absence of dysmorphic features described by Laron.

ALS, acid labile subunit; GH, growth hormone; IGF, insulin-like growth factor.

From Sperling MA: Pediatric endocrinology, *ed 4, Philadelphia, 2014, Elsevier, Box 10-4, p. 347.*

complete deficiencies of GH and prolactin and variable TSH deficiency. Affected patients exhibit nearly normal fetal growth but experience severe growth failure in the 1st yr of life. With normal production of LH and follicle-stimulating hormone, puberty develops spontaneously, though at a later than normal age. These patients are not at risk for development of ACTH deficiency. Anterior pituitary size is normal to small.

HESX1

The *HESX1* gene is expressed in precursors of all 5 cell types of the anterior pituitary early in embryologic development. Mutations result in a complex phenotype with defects in development of the optic nerve. Heterozygotes for loss-of-function mutations show the combinations of isolated GH deficiency and optic nerve hypoplasia. Homozygotes can have full expression of septooptic dysplasia. This condition combines incomplete development of the septum pellucidum with optic nerve hypoplasia and other midline abnormalities. Clinical observation of nystagmus and visual impairment in infancy leads to the discovery of optic nerve and brain abnormalities. Septooptic dysplasia is associated with anterior and/or posterior pituitary hormone deficiencies in approximately 25% of the cases. These patients often show the triad of a small anterior pituitary gland, an attenuated pituitary stalk, and an ectopic posterior pituitary bright spot. The great majority of patients with septooptic dysplasia do not have *HESX1* mutations. The etiology might involve mutations in another gene or a nongenetic explanation (see Chapters 591 and 631).

LHX3 and *LHX4*

The phenotype produced by recessive loss-of-function mutations of the *LHX3* gene resembles that produced by *PROP1* mutations. There are

*Pituitary tumors are classically the most common cause of hypopituitarism. However, new findings imply that causes related to brain damage might outnumber pituitary adenomas in causing hypopituitarism.

From Schneider HJ, Aimaretti G, Kreitschmann-Andermahr I, et al: Hypopituitarism, Lancet *369:1461–1470, 2007.*

deficiencies of GH, prolactin, TSH, LH, and follicle-stimulating hormone, but not ACTH. Some affected persons show enlargement of the anterior pituitary. The first patients to be described had the unusual findings of a short neck and a rigid cervical spine. They were only able to rotate their necks approximately 90 degrees compared with the normal rotation of 150-180 degrees. Dominantly inherited mutations in the structurally similar *LHX4* gene consistently produce GH deficiency, with the variable presence of TSH and ACTH deficiencies. Additional findings can include a very small V-shaped pituitary fossa, Chiari I malformation, and an ectopic posterior pituitary.

Other Congenital Forms

Pituitary hypoplasia can occur as an isolated phenomenon or in association with more extensive developmental abnormalities such as anencephaly or holoprosencephaly. Midfacial anomalies (cleft lip, palate; see Chapter 310) or the finding of a solitary maxillary central incisor indicates a high likelihood of GH or other anterior or posterior hormone deficiency. At least 12 genes have been implicated in the complex genetic etiology of holoprosencephaly (see Chapter 591.7). The Hall-Pallister syndrome is caused by dominant loss of function mutations in the *GLI3* gene. Absence of the pituitary gland is accompanied by hypothalamic hamartoblastoma, polydactyly, nail dysplasia, bifid epiglottis, imperforate anus, and anomalies of the heart, lungs, and kidneys. The combination of anophthalmia and hypopituitarism has been associated with mutations in the *SIX6, SOX2,* and *OTX2* genes.

Severe, early-onset MPHD including deficiency of ACTH is often associated with the triad of anterior pituitary hypoplasia, absence or attenuation of the pituitary stalk, and an ectopic posterior pituitary bright spot on MRI. Most cases are sporadic and there is a male predominance. Some are from abnormalities of the *SOX3* gene, located on the X chromosome. As with septooptic dysplasia, the majority of cases have not been explained at the genetic level.

Acquired Forms

Any lesion that damages the hypothalamus, pituitary stalk, or anterior pituitary can cause pituitary hormone deficiency (see Table 557-5). Because such lesions are not selective, multiple hormonal deficiencies are usually observed. Diabetes insipidus is more frequent in acquired than in congenital hypopituitarism. The most common lesion is the craniopharyngioma (see Chapter 497). Central nervous system germinoma, eosinophilic granuloma (histiocytosis), tuberculosis, sarcoidosis, toxoplasmosis, meningitis, and aneurysms can also cause hypothalamic-hypophyseal destruction. Trauma, including abusive head trauma (see Chapter 40), motor vehicle accidents, traction at delivery, anoxia, and hemorrhagic infarction, can also damage the pituitary, its stalk, or the hypothalamus.

ISOLATED GROWTH HORMONE DEFICIENCY AND INSENSITIVITY

Genetic Forms of Growth Hormone Deficiency

IGHD is caused by abnormalities of the GH-releasing hormone receptor, GH genes, and genes located on the X chromosome.

Growth Hormone–Releasing Hormone Receptor

Recessive loss-of-function mutations in the receptor for GH-releasing hormone interfere with proliferation of somatotropes during pituitary development and disrupt the most important signals for release of GH. The anterior pituitary is small, in keeping with the observation that somatotropes normally account for >50% of pituitary volume. There is some compromise of fetal growth followed by severe compromise of postnatal growth.

GH1

The *GH1* gene is one of a cluster of 5 genes on chromosome 17q22-24. This cluster arose through successive duplications of an ancestral GH gene. Unequal crossing over at meiosis has produced a variety of gene deletions. Small deletions (<10 kb) remove only the *GH1* gene, whereas large deletions (45 kb) remove 1 or more of the adjacent genes *(CSL, CS1, GH2,* and *CS2).* The growth phenotype is identical with deletion of *GH1* alone or *GH1* together with 1 or more of the adjacent genes. Loss of the *CS1, GH2,* and *CS2* genes without loss of *GH1* causes deficiency of chorionic somatomammotropin and placental GH in the maternal circulation, but it does not result in fetal or postnatal growth retardation. Most children with *GH1* gene deletions respond very well to recombinant GH treatment, but some develop antibodies to GH and cease growing.

Recessively transmitted mutations in the *GH1* gene produce a similar phenotype. Missense, nonsense, and frameshift mutations have been described. Autosomal dominant IGHD is also caused by mutations in *GH1.* The mutations usually involve splice-site errors in intron 3 and result in a variant protein that lacks the amino acids normally encoded by exon 3. Accumulation of this protein interferes with the processing, storage, and secretion of the normal GH protein and may result in additional deficiencies of TSH and/or ACTH. There are several reports of mutations in *GH1* that lead to variant proteins with reduced biological activity.

X-Linked Isolated Growth Hormone Deficiency

Two loci on the X chromosome have been associated with hypopituitarism. The first lies at Xq21.3-q22 in the region of the Bruton thymidine kinase *(BTK)* gene. Mutations in this region produce hypogammaglobulinemia as well as IGHD. The second locus maps farther out on the long arm, at Xq24-q27.1, a region containing the *SOX2* transcription factor gene. Abnormalities in this locus have been linked to IGHD with intellectual disability as well as to MPHD with the triad of pituitary hypoplasia, missing pituitary stalk, and ectopic posterior pituitary gland.

Acquired Forms

The GH axis is more susceptible to disruption by acquired conditions than are other hypothalamic-pituitary axes. Recognized causes of acquired GH deficiency include the use of radiotherapy for malignancy, meningitis, histiocytosis, and trauma.

Children who receive radiotherapy for central nervous system tumors or prevention of central nervous system malignancies (e.g., leukemia) are at risk for developing GH deficiency. Spinal irradiation contributes to disproportionately poor growth of the trunk. Growth typically slows during radiation therapy (see Chapter 718) or chemotherapy (see Chapter 494), improves for 1-2 yr, and then declines with the development of GH deficiency. The dose and frequency of radiotherapy are important determinants of hypopituitarism. GH deficiency is almost universal 5 yr after therapy with a total dose ≥35 Gy. More subtle defects are seen with doses around 20 Gy. Deficiency of GH is the most common defect, but deficiencies of TSH and ACTH can also occur. In contrast to other forms of hypopituitarism, puberty tends to be early rather than delayed (see Chapter 562.3). The clinician is likely to encounter children in the 8-10 yr age range who are growing at rates that are normal for chronological age but subnormal for stage of pubertal development.

GROWTH HORMONE INSENSITIVITY

Abnormalities of the Growth Hormone Receptor

GH insensitivity is caused by disruption of pathways distal to production of GH. Laron syndrome involves mutations of the GH receptor. Children with this condition clinically resemble those with severe IGHD. Birth length tends to be about 1 SD below the mean, and severe short stature with lengths >4 SD below the mean is present by 1 yr of age. Resting and stimulated GH levels tend to be high and insulin-like growth factor (IGF) 1 levels are low. The GH receptor has an extracellular GH-binding domain, a transmembrane domain, and an intracellular signaling domain. Mutations in the extracellular domain interfere with binding of GH. Serum GH-binding protein activity, representing the circulating form of the membrane receptor for GH, is generally low. Mutations in the transmembrane domain can interfere with anchoring of the receptor to the plasma membrane. In these cases, circulating GH-binding protein activity is normal or high. Mutations in the intracellular domain interfere with JAK/STAT signaling.

Postreceptor Forms of Growth Hormone Insensitivity

Some children with severe growth failure, high GH and low IGF-1 levels, and normal GH-binding protein levels have abnormalities distal to the GH binding and activation of the GH receptor. Several have been found to have mutations in the gene encoding signal transducer and activator of transcription 5b (STAT5b). Disruption of this key intermediate connecting receptor activation to gene transcription produces growth failure similar to that seen in Laron syndrome. These patients also suffer from chronic pulmonary infections, consistent with important roles for STAT5b in interleukin cytokine signaling.

IGF-1 Gene Abnormalities

Abnormalities of the *IGF-1* gene produce severe prenatal and postnatal growth impairment. Microcephaly, intellectual disability, and deafness are present in patients with exon deletion and a missense mutation. These patients can be expected to respond to recombinant IGF-1 treatment.

Insulin-Like Growth Factor–Binding Protein Abnormalities

Mutation of the gene encoding the acid labile subunit of the circulating 165-kDa IGF-1, IGF-BP3, acid labile subunit complex has been associated with short stature. Total IGF-1 levels were very low. The index case, with homozygosity for an acid labile subunit mutation, did not show an increase in IGF-1 levels or an increase in growth rate during GH treatment.

IGF-1 Receptor Gene Abnormalities

Mutations of the IGF-1 receptor also compromise prenatal and postnatal growth. The phenotype does not appear to be as severe as that seen with absence of IGF-1. Adult heights are closer to the normal range, and affected patients do not have intellectual disability or deafness.

CLINICAL MANIFESTATIONS

Congenital Hypopituitarism

The child with hypopituitarism is usually of normal size and weight at birth, although those with MPHD and genetic defects of the *GH1* or *GHR* gene have birth lengths that average 1 SD below the mean. Children with severe defects in GH production or action typically fall more than 4 SD below the mean for length by 1 yr of age. Those with less-severe deficiencies grow at rates below the 25th percentile for age and gradually diverge from normal height percentiles. Delayed closure of the epiphyses permits growth beyond the normal age when growth should be complete. Features of GH insensitivity are noted in Table 557-6.

Infants with congenital defects of the pituitary or hypothalamus may present with neonatal emergencies such as apnea, cyanosis, or severe hypoglycemia with or without seizures. Prolonged neonatal jaundice is common. It involves elevation of conjugated and unconjugated bilirubin and may be mistaken for neonatal hepatitis. Nystagmus can suggest septooptic dysplasia (see Chapter 591). Micropenis in boys provides an additional diagnostic clue. Deficiency of GH may be accompanied by hypoadrenalism (see Chapter 575) and hypothyroidism (see Chapter 565) as well as gonadotropin deficiency (see Chapters 583.2 and 586.2).

On physical examination, the head is round and the face is short and broad. The frontal bone is prominent, and the bridge of the nose is depressed and saddle shaped. The nose is small, and the nasolabial folds are well developed. The eyes are somewhat bulging. The mandible and the chin are underdeveloped, and the teeth, which erupt late, are often crowded. The neck is short and the larynx is small. The voice is high-pitched and remains high after puberty. The extremities are well proportioned, with small hands and feet. Weight for height is usually

Table 557-6	Clinical Features of Growth Hormone Insensitivity
Growth and development	
Birthweight: near-normal	
Birth length: may be slightly decreased	
Postnatal growth: severe growth failure	
Bone age: delayed, but may be advanced relative to height age	
Genitalia: micropenis in childhood; normal for body size in adults	
Puberty: delayed 3-7 yr	
Sexual function and fertility: normal	
Craniofacies	
Hair: sparse before the age of 7 yr	
Forehead: prominent; frontal bossing	
Skull: normal head circumference; craniofacial disproportion due to small facies	
Facies: small	
Nasal bridge: hypoplastic	
Orbits: shallow	
Dentition: delayed eruption	
Sclerae: blue	
Voice: high pitched	
Musculoskeletal/metabolic/miscellaneous	
Hypoglycemia: in infants and children; fasting symptoms in some adults	
Walking and motor milestones: delayed	
Hips: dysplasia; avascular necrosis of femoral head	
Elbow: limited extensibility	
Skin: thin, prematurely aged	
Osteopenia	

From Sperling MA: Pediatric endocrinology, *ed 4, Philadelphia, 2014, Elsevier, Table 10-5, p. 355.*

normal, but an excess of body fat and a deficiency of muscle mass contribute to a pudgy appearance. The genitals are usually small for age, and sexual maturation may be delayed or absent. Facial, axillary, and pubic hair usually is lacking, and the scalp hair is fine. Intelligence is usually normal for age and the children may seem precocious compared to children of a similar size.

Acquired Hypopituitarism

The child is normal initially, and manifestations similar to those seen in idiopathic pituitary growth failure gradually appear and progress. When complete or almost complete destruction of the pituitary gland occurs, signs of pituitary insufficiency are present. Atrophy of the adrenal cortex, thyroid, and gonads results in loss of weight, asthenia, sensitivity to cold, mental torpor, and absence of sweating. Sexual maturation fails to take place or regresses if already present. There may be atrophy of the gonads and genital tract with amenorrhea and loss of pubic and axillary hair. There is a tendency to hypoglycemia. Growth slows dramatically. Diabetes insipidus (see Chapter 558) may be present but tends to improve spontaneously with development of central adrenal insufficiency.

If the lesion is an expanding tumor, symptoms such as headache, vomiting, visual disturbances, pathologic sleep patterns, decreased school performance, seizures, polyuria, and growth failure can occur (see Chapter 497). Slowing of growth can antedate neurologic signs and symptoms, especially with craniopharyngiomas. Evidence of pituitary insufficiency may first appear after surgical intervention. In children with craniopharyngiomas, visual field defects, optic atrophy, papilledema, and cranial nerve palsy are common.

LABORATORY FINDINGS

GH deficiency should be suspected in children with severe postnatal growth failure (Table 557-7). Criteria for growth failure include height below the 1st percentile for age and sex or height >2 SD below sex-adjusted mid-parent height. Acquired GH deficiency can occur at any age, and when it is of acute onset, height may be within the normal range. A strong clinical suspicion is important in establishing the diagnosis because laboratory measures of GH sufficiency lack specificity. Observation of low serum levels of IGF-1 and the GH-dependent IGF-BP3 can be helpful, but IGF-1 and IGF-BP3 levels should be matched to normal values for skeletal age rather than chronological age. Values in the upper part of the normal range for age effectively exclude GH deficiency. IGF-1 values in normally growing children and those with hypopituitarism overlap during infancy and early childhood.

Definitive diagnosis of GH deficiency traditionally requires demonstration of absent or low levels of GH in response to stimulation. A variety of provocative tests have been devised that rapidly increase the level of GH in normal children. These include administration of insulin, arginine, clonidine, or glucagon. In chronic GH deficiency, the demonstration of subnormal linear growth, a delayed skeletal age, and low peak levels of GH (<10 ng/mL) in each of 2 provocative tests are compatible with GH deficiency. In acute GH deficiency, a high clinical suspicion of GH deficiency and low peak levels of GH (<10 ng/mL) in each of 2 provocative tests are compatible with GH deficiency. This rather arbitrary cutoff point is higher than the 3 or 5 ng/mL criteria used for diagnosis of adult GH deficiency. There is no consensus regarding adoption of criteria that take into account age, sex, and GH assay characteristics. Some studies indicate that a majority of normal prepubertal children fail to achieve GH values >10 ng/mL with 2 pharmacologic tests. The researchers suggest that 3 days of estrogen priming should be used before GH testing to achieve greater diagnostic specificity.

In addition to establishing the diagnosis of GH deficiency, it is necessary to examine other pituitary functions. Levels of TSH, free thyroxine, ACTH, cortisol, gonadotropins, and gonadal steroids might provide evidence of other pituitary hormonal deficiencies. Antidiuretic hormone deficiency may be established by appropriate studies.

Table 557-7 Evaluation of Suspected Growth Hormone Deficiency

Growth-related history and patient physical exam	• Infants and children with GHD have growth failure • Short stature and growth failure may be the only clinical features present • GHD affects ~1 in 3,500 children
Imaging and other evaluations	• Diagnosis is based on clinical, auxologic, and biochemical parameters • Radiologic evaluation of bone age • Central nervous system MRI or CT scan to evaluate the hypothalamic-pituitary region and to exclude other conditions • Evaluation and management by a pediatric endocrinologist
Laboratory evaluation	• Measurements of GH, IGF-1, and IGF-1–binding protein levels • Determination of peak GH levels after stimulation test
Special testing (if applicable)	• Family history and genetic analyses (e.g., search for *PROP1* and *POU1F1* mutations)
Rationale for treatment and treatment modalities	• Replacement therapy with rhGH (GHT) • Predictors of greater benefit with GHT in GHD include early initiation of treatment, higher rhGH dose, and IGF-1–guided dosing • GHT should be started as soon as GHD is diagnosed

GH, growth hormone; GHD, growth hormone deficiency; GHT, growth hormone therapy; IGF, insulin-like growth factor; *POU1F1,* POU class 1 homeobox 1; *PROP1,* homeobox protein prophet of Pit1; rhGH, human recombinant growth hormone.

From Rogol AD, Hayden GF: Etiologies and early diagnosis of short stature and growth failure in children and adolescents. J Pediatr *164(5):S1–S14, 2014, Table XIII, p. S10.*

RADIOLOGIC FINDINGS

Conventional x-ray films of the skull have been replaced by CT and MRI. CT is appropriate for recognizing suprasellar calcification associated with craniopharyngiomas and bony changes accompanying histiocytosis. MRI provides a much more detailed view of hypothalamic and pituitary anatomy. Many cases of severe early-onset MPHD show the triad of a small anterior pituitary gland, a missing or attenuated pituitary stalk, and an ectopic posterior pituitary bright spot at the base of the hypothalamus. Subnormal anterior pituitary height, implying a small anterior pituitary, is common in genetic and idiopathic causes of IGHD. Craniopharyngiomas are common and pituitary adenomas are rare in children with hypopituitarism. Both hypoplastic and markedly enlarged anterior pituitary glands are seen in patients with *PROP1* or *LHX3* mutations.

Skeletal maturation is delayed in patients with IGHD and may be even more delayed when there is combined GH and TSH deficiency. Dual-photon x-ray absorptiometry shows deficient bone mineralization, deficiencies in lean body mass, and a corresponding increase in adiposity.

DIFFERENTIAL DIAGNOSIS

The causes of growth disorders are legion. Systemic conditions, such as inflammatory bowel disease, celiac disease, occult renal disease, and anemia, must be considered. Patients with systemic conditions often have greater loss of weight than length. A few otherwise normal children are short (i.e., >3 SD below the mean for age) and grow 5 cm/yr or less but have normal levels of GH in response to provocative tests and normal spontaneous episodic secretion. Most of these children show increased rates of growth when treated with GH in doses comparable to those used to treat children with hypopituitarism. Plasma levels of IGF-1 in these patients may be normal or low. Several groups of treated children have achieved final or near-final adult heights. Different studies have found changes in adult height that range from −2.5 to +7.5 cm compared with pretreatment predictions. There are no methods that can reliably predict which of these children will become

taller in adulthood as a result of GH treatment and which will have compromised adult height.

Diagnostic strategies for distinguishing between permanent GH deficiency and other causes of impaired growth are imperfect. Children with a combination of genetic short stature and constitutional delay of growth have short stature, below-average growth rates, and delayed bone ages. Many of these children exhibit minimal GH secretory responses to provocative stimuli. When children in whom idiopathic or acquired GH deficiency is diagnosed are treated with human GH (hGH) and retested as adults, the majority have peak GH levels within the normal range.

Constitutional Growth Delay

Constitutional growth delay is one of the variants of normal growth commonly encountered by the pediatrician. Length and weight measurements of affected children are normal at birth, and growth is normal for the 1st 4-12 mo of life. Height is sustained at a lower percentile during childhood. The pubertal growth spurt is delayed, so their growth rates continue to decline after their classmates have begun to accelerate. Detailed questioning often reveals other family members (often 1 or both parents) with histories of short stature in childhood, delayed puberty, and eventual normal stature. IGF-1 levels tend to be low for chronological age but within the normal range for bone age. GH responses to provocative testing tend to be lower than in children with a more typical timing of puberty. The prognosis for these children to achieve normal adult height is guarded. Predictions based on height and bone age tend to overestimate eventual height to a greater extent in boys than in girls. Boys with >2 yr of pubertal delay can benefit from a short course of testosterone therapy to hasten puberty after 14 yr of age. The cause of this variant of normal growth is thought to be persistence of the relatively hypogonadotropic state of childhood (see Chapter 15).

Primary Hypothyroidism

Primary hypothyroidism (see Chapter 565) is more common than GH deficiency. Low total or free thyroxine and elevated TSH levels establish the diagnosis. Responses to GH provocative tests may be subnormal and the sella may be enlarged. Pituitary hyperplasia recedes during treatment with thyroid hormone. Because thyroid hormone is a necessary prerequisite for normal GH synthesis, it must always be assessed before GH evaluation.

Psychosocial Causes

Emotional deprivation is an important cause of retardation of growth and mimics hypopituitarism. The condition is known as *psychosocial dwarfism, maternal deprivation dwarfism*, or *hyperphagic short stature*. The mechanisms by which sensory and emotional deprivation interfere with growth are not fully understood. Functional hypopituitarism is indicated by low levels of IGF-1 and by inadequate responses of GH to provocative stimuli. Puberty may be normal or even premature. Appropriate history and careful observations reveal disturbed mother–child or family relations and provide clues to the diagnosis (see Chapter 40). Proof may be difficult to establish because the parents or caregivers often hide the true family situation from professionals, and the children rarely divulge their plight. Emotionally deprived children often have perverted or voracious appetites, enuresis, encopresis, insomnia, crying spasms, and sudden tantrums. The subgroup of children with hyperphagia and a normal body mass index tends to show catch-up growth when placed in a less stressful environment.

TREATMENT

Recombinant hGH has been available by prescription since 1982. There are currently 8 brands marketed in the United States. They are therapeutically equivalent, with the major differences consisting of proprietary devices for subcutaneous injection and availability of solubilized liquid forms or powders needing reconstitution before injection. At present none of the products are available in long-acting repository forms.

The FDA has approved 8 indications for GH treatment to promote growth. They are GH deficiency, Turner syndrome, chronic renal failure before transplantation, idiopathic short stature, small-for-gestational age short stature, Prader-Willi syndrome, *SHOX* gene abnormality, and Noonan syndrome. FDA approval for a given indication does not ensure that a patient's third-party insurance carrier will approve payment for the drug. The Pediatric Endocrine Society, the Academy of Pediatrics, and the GH Research Society have published guidelines for hGH treatment of children with classic GH deficiency. Treatment should be started as soon as possible to narrow the gap in height between patients and their classmates during childhood and to have the greatest effect on mature height. The recommended dose of hGH is 0.18-0.3 mg/kg/wk during childhood. Higher doses have been used during puberty. Recombinant GH is administered subcutaneously in 6 or 7 divided doses. Maximal response to GH occurs in the 1st yr of treatment. Growth velocity during this 1st yr is typically above the 95th percentile for age. With each successive yr of treatment, the growth rate tends to decrease. If growth rate drops below the 25th percentile, compliance should be evaluated before the dose is increased.

Concurrent treatment with GH and a gonadotropin-releasing hormone agonist has been used in the hope that interruption of puberty will delay epiphyseal fusion and prolong growth. This strategy can increase adult height. It can also increase the discrepancy in physical maturity between GH-deficient children and their age peers and can impair bone mineralization. There have also been attempts to forestall epiphyseal fusion in boys by giving drugs that inhibit aromatase, the enzyme responsible for converting androgens to estrogens. Therapy should be continued until near-final height is achieved. Criteria for stopping GH treatment include a decision by the patient that he or she is tall enough, a growth rate <1 inch/yr, and a bone age >14 yr in girls and >16 yr in boys.

Some patients develop either primary or central hypothyroidism while under treatment with GH. Similarly, there is a risk of developing adrenal insufficiency. If unrecognized, this can be fatal. Periodic evaluation of thyroid and adrenal function is indicated for all patients treated with GH.

Recombinant IGF-1 is approved for use in the United States. It is given subcutaneously twice a day. The risk of hypoglycemia is reduced by giving the injections concurrently with a meal or snack. In some situations its use is more efficacious than use of GH. These conditions include abnormalities of the GH receptor and *STAT5b* genes, as well as severe GH deficiency in patients who have developed antibodies to administered GH. Its utility in improving growth rate and adult stature in broader categories of short children is being explored.

The doses of GH used to treat children with classic GH deficiency usually enhance the growth of many non–GH-deficient children as well. Intensive investigation is in progress to determine the full spectrum of short children who may benefit from treatment with GH. The FDA approval for use of GH in idiopathic short stature specifies a height below the 1.2 percentile (–2.25 SD) for age and sex, a predicted height below the 5th percentile, and open epiphyses. Studies of the effect of GH treatment on adult height suggest a median gain of 2-3 inches, depending on dose and duration of treatment.

In children with MPHD, replacement should also be directed at other hormonal deficiencies. In TSH-deficient patients, thyroid hormone is given in full replacement doses. In ACTH-deficient patients, the optimal dose of hydrocortisone should not exceed 10 mg/m^2/24 hr. Increases of 2-3–fold are made to provide stress coverage during illness or in anticipation of surgical procedures. In patients with a deficiency of gonadotropins, gonadal steroids are given when bone age reaches the age at which puberty usually takes place. For infants with micropenis, 1 or 2 three-month courses of monthly intramuscular injections of 25 mg of testosterone cypionate or testosterone enanthate can bring the penis to normal size without an inordinate effect on osseous maturation.

COMPLICATIONS AND ADVERSE EFFECTS OF GH TREATMENT

GH treatment influences glucose homeostasis. Fasting and postprandial insulin levels are characteristically low before treatment, and they normalize during GH replacement. Recent studies indicate that GH

treatment is associated with a 6-fold increase in the risk for type 2 diabetes and no significant increase in the risk for type 1 diabetes.

Concerns have been raised about the safety of GH treatment in children who become deficient after treatment of brain tumors, leukemia, and other neoplasms. Long-term studies show no increase in risk of recurrence of craniopharyngioma, other brain tumors, or leukemia. At least 3 studies indicate an increased risk of second neoplasms in cancer survivors treated with GH. An unconfirmed study documents a 30% increase in mortality among young adults who received GH in childhood. There appears to be a correlation between risk of mortality and GH doses >0.35 mg/kg/wk.

Other reported side effects include pseudotumor cerebri, slipped capital femoral epiphysis, gynecomastia, and worsening of scoliosis, and in adults treated as a child there is an increased risk of hemorrhagic stroke. The risk of later development of Creutzfeldt-Jakob disease was limited to recipients of contaminated lots of extracted pituitary GH. No comparable risks have been seen with recombinant hGH.

Chapter 558

Diabetes Insipidus

David T. Breault and Joseph A. Majzoub

Diabetes insipidus (DI) manifests clinically with polyuria and polydipsia and can result from either vasopressin deficiency (central DI) or vasopressin insensitivity at the level of the kidney (nephrogenic DI). Both central DI and nephrogenic DI can arise from inherited defects of congenital or neonatal onset or can be secondary to a variety of causes (Table 558-1).

PHYSIOLOGY OF WATER BALANCE

The control of extracellular tonicity (osmolality) and volume within a narrow range is critical for normal cellular structure and function (see Chapter 55.2). Extracellular fluid tonicity is regulated almost exclusively by water intake and excretion, whereas extracellular volume is regulated by sodium intake and excretion. The control of plasma tonicity and intravascular volume involves a complex integration of endocrine, neural, behavioral, and paracrine systems (Fig. 558-1). Vasopressin, secreted from the posterior pituitary, is the principal regulator of tonicity, with its release largely stimulated by increases in plasma tonicity. Volume homeostasis is largely regulated by the renin–angiotensin–aldosterone system, with contributions from both vasopressin and the natriuretic peptide family.

Vasopressin, a 9-amino-acid peptide, has both antidiuretic and vascular pressor activity and is synthesized in the paraventricular and supraoptic nuclei of the hypothalamus. It is transported to the posterior pituitary via axonal projections, where it is stored awaiting release into the systemic circulation. The half-life of vasopressin in the circulation is 5 min. In addition to responding to osmotic stimuli, vasopressin is secreted in response to significant decreases in intravascular volume and pressure (minimum of 8% decrement) via afferent baroreceptor pathways arising from the aortic arch (carotid sinus) and volume receptor pathways in the cardiac atria and pulmonary veins. Osmotic and hemodynamic stimuli interact synergistically.

The sensation of thirst is regulated by cortical as well as hypothalamic neurons. The thirst threshold is approximately 10 mOsm/kg higher (i.e., 293 mOsm/kg) than the osmotic threshold for vasopressin release. Consequently, under conditions of hyperosmolality, vasopressin is released before thirst is initiated, allowing ingested water to be retained. Chemoreceptors present in the oropharynx rapidly downregulate vasopressin release following water ingestion.

Vasopressin exerts its principal effect on the kidney via V2 receptors located primarily in the collecting tubule, the thick ascending limb of the loop of Henle, and the periglomerular tubules. The human V2 receptor gene is located on the long arm of the X chromosome (Xq28) at the locus associated with **congenital, X-linked, vasopressin-resistant DI.** Activation of the V2 receptor results in increases in intracellular cyclic adenosine monophosphate, which leads to the insertion of the aquaporin-2 water channel into the apical (luminal) membrane. This allows water movement along its osmotic gradient into the hypertonic inner medullary interstitium from the tubule lumen and excretion of concentrated urine. In contrast to aquaporin-2,

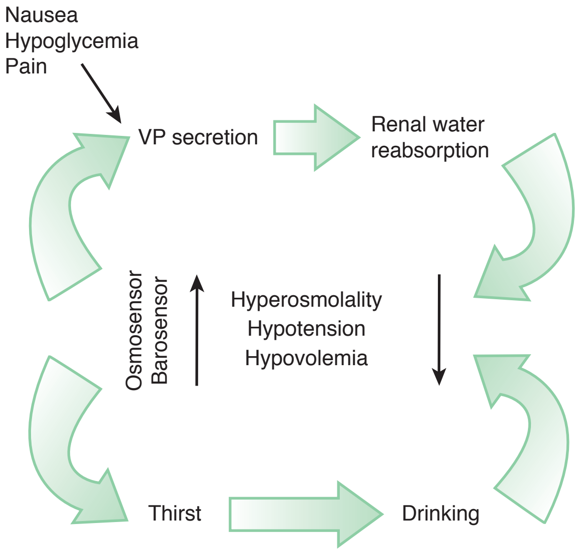

Figure 558-1 Regulation of vasopressin (VP) secretion and serum osmolality. Hyperosmolality, hypovolemia, and hypotension are sensed by osmosensors, volume sensors, and barosensors, respectively. These stimulate both VP secretion and thirst. VP, acting on the kidney, causes increased reabsorption of water (antidiuresis). Thirst causes increased water ingestion. The results of these dual negative feedback loops cause a reduction in hyperosmolality or in hypotension or hypovolemia. Additional stimuli for VP secretion include nausea, hypoglycemia, and pain. *(From Muglia LJ, Majzoub JA: Disorders of the posterior pituitary. In Sperling MA, editor:* Pediatric endocrinology, *ed 4, Philadelphia, 2014, Elsevier, Fig. 6.)*

aquaporin-3 and aquaporin-4 are expressed on the basolateral membrane of the collecting duct cells and aquaporin-1 is expressed in the proximal tubule. These channels may also contribute to urinary concentrating ability.

Atrial natriuretic peptide, initially isolated from cardiac atrial muscle, has a number of important effects on salt and water balance, including stimulation of natriuresis, inhibition of sodium resorption, and inhibition of vasopressin secretion. Atrial natriuretic peptide is expressed in endothelial cells and vascular smooth muscle, where it appears to regulate relaxation of arterial smooth muscle. Atrial natriuretic peptide is also expressed in the brain, along with other natriuretic family members; the physiologic role of these factors has yet to be defined.

APPROACH TO THE PATIENT WITH POLYURIA, POLYDIPSIA, AND HYPERNATREMIA

The cause of pathologic polyuria or polydipsia (exceeding 2 L/m^2/24 hr) may be difficult to establish in children. Infants can present with irritability, failure to thrive, and intermittent fever. Patients with suspected DI should have a careful history taken, which should quantify the child's daily fluid intake and output and establish the voiding pattern, nocturia, and primary or secondary enuresis. A complete physical examination should establish the patient's hydration status, and the physician should search for evidence of visual and central nervous system dysfunction, as well as for other pituitary hormone deficiencies.

If pathologic polyuria or polydipsia is present, the following should be obtained: serum for osmolality, sodium, potassium, blood urea nitrogen, creatinine, glucose, and calcium; urine for osmolality, specific gravity, and glucose determination. The diagnosis of DI is established if the serum osmolality is >300 mOsm/kg and the urine osmolality is <300 mOsm/kg. DI is unlikely if the serum osmolality is <270 mOsm/kg or the urine osmolality is >600 mOsm/kg. If the patient's serum osmolality is <300 mOsm/kg (but >270 mOsm/kg) and pathologic polyuria and polydipsia are present, a water deprivation test is indicated to establish the diagnosis of DI and to differentiate central from nephrogenic causes.

In the inpatient postneurosurgical setting, central DI is likely if hyperosmolality (serum osmolality >300 mOsm/kg) is associated with urine osmolality less than serum osmolality. It is important to distinguish between polyuria resulting from postsurgical central DI and polyuria resulting from the normal diuresis of fluids received intraoperatively. Both cases may be associated with a large volume (>200 mL/m^2/hr) of dilute urine, although in patients with DI, the serum osmolality is high in comparison with patients undergoing postoperative diuresis.

CAUSES OF HYPERNATREMIA

Hypernatremia is discussed in Chapter 55.3.

Central Diabetes Insipidus

Central DI can result from multiple etiologies, including genetic mutations in the vasopressin gene; trauma (accidental or surgical) to vasopressin neurons; congenital malformations of the hypothalamus or pituitary; neoplasms; infiltrative, autoimmune, and infectious diseases affecting vasopressin neurons or fiber tracts; and increased metabolism of vasopressin. In approximately 10% of children with central DI, the etiology is idiopathic. Other pituitary hormone deficiencies may be present (see Chapter 557). Over time, up to 35% of those with idiopathic central DI will develop other hormone deficiencies or have an underlying etiology identified.

Autosomal dominant central DI usually occurs within the 1st 5 yr of life and results from mutations in the vasopressin gene. A number of mutations can cause gene-processing defects in a subset of vasopressin-expressing neurons, which have been postulated to result in endoplasmic reticulum stress and cell death. **Wolfram syndrome,** which includes DI, diabetes mellitus, optic atrophy, and deafness, also results in vasopressin deficiency. Mutations in 2 genes, which give rise to endoplasmic reticulum proteins, are associated with this condition. Congenital brain abnormalities (see Chapter 591) such as **optic nerve hypoplasia syndrome** with agenesis of the corpus callosum, the Niikawa-Kuroki syndrome, holoprosencephaly, and familial pituitary hypoplasia with absent stalk may be associated with central DI and defects in thirst perception. Empty sella syndrome, possibly resulting from unrecognized pituitary infarction (see Chapter 557), can be associated with DI in children.

Trauma to the base of the brain and neurosurgical intervention in the region of the hypothalamus or pituitary are common causes of central DI. The **triphasic response** following surgery refers to an initial phase of transient DI, lasting 12-48 hr, followed by a 2nd phase of syndrome of inappropriate antidiuretic hormone secretion, lasting up to 10 days, which may be followed by permanent DI. The initial phase may be the result of local edema interfering with normal vasopressin secretion; the 2nd phase results from unregulated vasopressin release from dying neurons, whereas in the 3rd phase, permanent DI results if more than 90% of the neurons have been destroyed.

Given the anatomic distribution of vasopressin neurons over a large area within the hypothalamus, tumors that cause DI must either be very large and infiltrative or be strategically located near the base of the hypothalamus, where vasopressin axons converge before their entry into the posterior pituitary. Germinomas and pinealomas typically arise in this region and are among the most common primary brain tumors associated with DI. Germinomas can be very small and undetectable by MRI for several years following the onset of polyuria. Quantitative measurement of α-fetoprotein and β-human chorionic gonadotropin, often secreted by germinomas, should be performed in children with idiopathic or unexplained DI in addition to serial MRI scans. Craniopharyngiomas and optic gliomas can also cause central DI when they are very large, although this is more often a postoperative complication of the treatment for these tumors (see Chapter 497). Hematologic malignancies, such as acute myelocytic leukemia, can cause DI via infiltration of the pituitary stalk and sella.

Langerhans cell histiocytosis (see Chapter 507) and lymphocytic hypophysitis are common types of infiltrative disorders causing central DI, with **hypophysitis** as the cause in 50% of cases of "idiopathic" central DI. Infections involving the base of the brain (see Chapter 603), including meningitis (meningococcal, cryptococcal, listerial, toxoplasmal), congenital cytomegalovirus infection, and nonspecific inflammatory diseases of the brain may give rise to central DI that is often transient. Drugs associated with the inhibition of vasopressin release include ethanol, phenytoin, opiate antagonists, halothane, and α-adrenergic agents.

Nephrogenic Diabetes Insipidus

Nephrogenic (vasopressin-insensitive) DI (NDI) can result from genetic or acquired causes. Genetic causes are less common but more severe than acquired forms of NDI. The polyuria and polydipsia associated with genetic NDI usually occur within the 1st several wk of life, but may only become apparent after weaning or with longer periods of nighttime sleep. Many infants initially present with fever, vomiting, and dehydration. Failure to thrive may be secondary to the ingestion of large amounts of water, resulting in caloric malnutrition. Long-standing ingestion and excretion of large volumes of water can lead to nonobstructive hydronephrosis, hydroureter, and megabladder.

Congenital X-linked NDI results from inactivating mutations of the vasopressin V2 receptor. **Congenital autosomal recessive NDI** results from defects in the aquaporin-2 gene. An **autosomal dominant form of NDI** is associated with processing mutations of the aquaporin-2 gene.

Acquired NDI can result from hypercalcemia or hypokalemia and is associated with lithium, demeclocycline, foscarnet, clozapine, amphotericin, methicillin, and rifampin. Impaired renal concentrating ability can also be seen with ureteral obstruction, chronic renal failure, polycystic kidney disease, medullary cystic disease, Sjögren syndrome, and sickle cell disease. Decreased protein or sodium intake or excessive water intake, as in primary polydipsia, can lead to diminished tonicity of the renal medullary interstitium and NDI.

TREATMENT OF CENTRAL DIABETES INSIPIDUS

Fluid Therapy

With an intact thirst mechanism and free access to oral fluids, a person with complete DI can maintain plasma osmolality and sodium in the high normal range, although at great inconvenience. Neonates and young infants are often best treated solely with fluid therapy, given their requirement for large volumes (3 L/m^2/24 hr) of nutritive fluid. The use of vasopressin analogs in patients with obligate high fluid intake is difficult given the risk of life-threatening hyponatremia. Although not FDA approved, the use of diluted parenteral and lyophilized long-acting vasopressin analog DDAVP (desmopressin) has been successfully administered to infants with central DI both subcutaneously and orally without causing severe hyponatremia.

Vasopressin Analogs

Treatment of central DI in older children is best accomplished with the use of DDAVP. DDAVP is available in an intranasal preparation (onset 5-10 min) and as tablets (onset 15-30 min). The intranasal preparation of DDAVP (10 µg/0.1 mL) can be administered by rhinal tube (allowing dose titration) or by nasal spray. Use of DDAVP oral tablets requires at least a 10-fold increase in the dosage compared with the intranasal preparation. Oral dosages of 25-300 µg every 8-12 hr are safe and effective in children. The appropriate dosage and route of administration is determined empirically based on the desired length of antidiuresis and patient preference. The use of DDAVP nasal spray (10 µg/0.1 mL) for the treatment of primary enuresis in older children should be regarded as a temporizing measure, given it does not affect the underlying condition, and should be used with great caution given the risk of hyponatremia if water intake exceeds the capacity for renal clearance. To prevent water intoxication, patients should have at least 1 hr of urinary breakthrough between doses each day and be advised to drink in response to thirst sensation.

Aqueous Vasopressin

Central DI of acute onset following neurosurgery is best managed with continuous administration of synthetic aqueous vasopressin (Pitressin). Under most circumstances, total fluid intake must be limited to 1 L/m^2/24 hr during antidiuresis. A typical dosage for intravenous vasopressin therapy is 1.5 mU/kg/hr, which results in a blood vasopressin concentration of approximately 10 pg/mL. On occasion, following hypothalamic (but not transsphenoidal) surgery, higher initial concentrations of vasopressin may be required to treat acute DI, which has been attributed to the release of a vasopressin inhibitory substance. Vasopressin concentrations >1,000 pg/mL should be avoided because they can cause cutaneous necrosis, rhabdomyolysis, cardiac rhythm disturbances, and hypertension. Postneurosurgical patients treated with vasopressin infusion should be switched from intravenous to oral fluids as soon as possible to allow thirst sensation, if intact, to help regulate osmolality.

TREATMENT OF NEPHROGENIC DIABETES INSIPIDUS

The treatment of acquired NDI focuses on eliminating, if possible, the underlying disorder, such as offending drugs, hypercalcemia, hypokalemia, or ureteral obstruction. Congenital nephrogenic DI is often difficult to treat. The main goals are to ensure the intake of adequate calories for growth and to avoid severe dehydration. Foods with the highest ratio of caloric content to osmotic load (Na <1 mmol/kg/24 hr) should be ingested to maximize growth and to minimize the urine volume required to excrete the solute load. Even with the early institution of therapy, however, growth failure and developmental disabilities are common.

Pharmacologic approaches to the treatment of NDI include the use of thiazide diuretics and are intended to decrease the overall urine output. Thiazides appear to induce a state of mild volume depletion by enhancing sodium excretion at the expense of water and by causing a decrease in the glomerular filtration rate, which results in proximal tubular sodium and water reabsorption. Indomethacin and amiloride may be used in combination with thiazides to further reduce polyuria. High-dose DDAVP therapy, in combination with indomethacin, has been used in some subjects with NDI. This treatment could prove useful in patients with genetic defects in the V2 receptor associated with a reduced binding affinity for vasopressin.

Chapter 559

Other Abnormalities of Arginine Vasopressin Metabolism and Action

David T. Breault and Joseph A. Majzoub

Hyponatremia (serum sodium <130 mEq/L) in children is usually associated with severe systemic disorders and is most often a result of intravascular volume depletion, excessive salt loss, or hypotonic fluid overload, especially in infants (see Chapter 55).

The initial approach to the patient with hyponatremia begins with determination of the volume status. A careful review of the patient's history, physical examination (including changes in weight), and vital signs helps determine whether the patient is hypovolemic or hypervolemic. Supportive evidence includes laboratory data such as serum electrolytes, blood urea nitrogen, creatinine, uric acid, urine sodium, specific gravity, and osmolality (see Chapter 55; Tables 559-1 and 559-2).

Table 559-1 Differential Diagnosis of Hyponatremia

DISORDER	INTRAVASCULAR VOLUME STATUS	URINE SODIUM
Systemic dehydration	Low	Low
Decreased effective plasma volume	Low	Low
Primary salt loss (nonrenal)	Low	Low
Primary salt loss (renal)	Low	High
SIADH	High	High
Cerebral salt wasting	Low	Very high
Decreased free water clearance	Normal or high	Normal or high
Primary polydipsia	Normal or high	Normal
Runner's hyponatremia	Low	Low
NSIAD	High	High
Pseudohyponatremia	Normal	Normal
Factitious hyponatremia	Normal	Normal

NSIAD, nephrogenic syndrome of inappropriate antidiuresis; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

Table 559-2 Clinical Parameters to Distinguish Among SIADH, Cerebral Salt Wasting, and Central Diabetes Insipidus

CLINICAL PARAMETER	SIADH	CEREBRAL SALT WASTING	CENTRAL DI
Serum sodium	Low	Low	High
Urine output	Normal or low	High	High
Urine sodium	High	Very high	Low
Intravascular volume status	Normal or high	Low	Low
Vasopressin level	High	Low	Low

DI, diabetes insipidus; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

CAUSES OF HYPONATREMIA

Syndrome of Inappropriate Antidiuretic Hormone Secretion

Syndrome of inappropriate antidiuretic hormone secretion (SIADH) is characterized by hyponatremia, an inappropriately concentrated urine (>100 mOsm/kg), normal or slightly elevated plasma volume, normal-to-high urine sodium, and low serum uric acid. SIADH is uncommon in children, and most cases result from excessive administration of vasopressin in the treatment of central diabetes insipidus. It can also occur with encephalitis, brain tumors, head trauma, psychiatric disease, prolonged nausea, pneumonia, tuberculous meningitis, and AIDS and in the postictal phase following generalized seizures. SIADH is the cause of the hyponatremic second phase of the triphasic response seen after hypothalamic–pituitary surgery (see Chapter 558). It is found in up to 35% of patients 1 wk after surgery and can result from retrograde neuronal degeneration with cell death and vasopressin release. Common drugs that have been shown to increase vasopressin secretion or mimic vasopressin action, resulting in hyponatremia, include oxcarbazepine, carbamazepine, chlorpropamide, vinblastine, vincristine, and tricyclic antidepressants.

Nephrogenic Syndrome of Inappropriate Antidiuresis

Gain-of-function mutations in the V2 vasopressin receptor gene have been described in male infants presenting with an SIADH-like clinical picture with undetectable vasopressin levels. Activating mutations in the aquaporin-2 gene might also give rise to the same syndrome but have not yet been described.

Systemic Dehydration

The initial manifestation of systemic dehydration is often hypernatremia and hyperosmolality, which subsequently lead to the activation of vasopressin secretion and a decrease in water excretion. As dehydration progresses, hypovolemia and/or hypotension become a major stimulus for vasopressin release, further decreasing free water clearance. Excessive free water intake with ongoing salt loss can also produce hyponatremia. Urinary sodium excretion is low (usually <10 mEq/L) owing to a low glomerular filtration rate and concomitant activation of the renin–angiotensin–aldosterone system, unless primary renal disease or diuretic therapy is present.

Primary Salt Loss

Hyponatremia can result from the primary loss of sodium chloride as seen in specific disorders of the kidney (congenital polycystic kidney disease, acute interstitial nephritis, chronic renal failure), gastrointestinal tract (gastroenteritis), and sweat glands (cystic fibrosis). The hyponatremia is not solely caused by the salt loss, because the latter also causes hypovolemia, leading to an increase in vasopressin. Mineralocorticoid deficiency (hypoaldosteronism), pseudohypoaldosteronism (genetic or sometimes seen in children with urinary tract obstruction or infection), and diuretics can also result in loss of sodium chloride. Hypoaldosterone states are associated with salt wasting, hypovolemia, hyponatremia, hyperkalemia, and failure to thrive (Table 559-3).

Decreased Effective Plasma Volume

Hyponatremia can result from decreased effective plasma volume, as found in congestive heart failure, cirrhosis, nephrotic syndrome, positive pressure mechanical ventilation, severe burns, bronchopulmonary dysplasia in neonates, cystic fibrosis with obstruction, and severe asthma. The resulting decrease in cardiac output leads to reduced water and salt excretion, as with systemic dehydration, and an increase in vasopressin secretion. In patients with impaired cardiac output and elevated atrial volume (congestive heart failure, lung disease), atrial natriuretic peptide concentrations are elevated further, leading to hyponatremia by promoting natriuresis. However, owing to the marked elevation of aldosterone in these patients, their urine sodium remains low (<20 mEq/L) despite this. Unlike dehydrated patients, these patients also have excess total body sodium from activation of the renin–angiotensin–aldosterone system and can demonstrate peripheral edema as well.

Primary Polydipsia (Increased Water Ingestion)

In patients with normal renal function, the kidney can excrete dilute urine with an osmolality as low as 50 mOsm/kg. To excrete a daily solute load of 500 mOsm/m^2, the kidney must produce 10 L/m^2 of urine per day. Therefore, to avoid hyponatremia, the maximum amount of water a person with normal renal function can consume is 10 L/m^2. Neonates, however, cannot dilute their urine to this degree, putting them at risk for water intoxication if water intake exceeds 4 L/m^2/day (approximately 60 mL/hr in a newborn). Many infants develop transient but symptomatic hyponatremic seizures after being fed pure water without electrolytes rather than breast milk or formula.

Decreased Free Water Clearance

Hyponatremia as a consequence of decreased renal free water clearance, even in the absence of an increase in vasopressin secretion, can result from adrenal insufficiency or thyroid deficiency or can be related to a direct effect of drugs on the kidney. Both mineralocorticoids and glucocorticoids are required for normal free water clearance in a vasopressin-independent manner. In patients with unexplained hyponatremia, adrenal and thyroid insufficiency should be considered. In addition, patients with coexisting adrenal failure and diabetes insipidus might have no symptoms of the latter until glucocorticoid therapy unmasks the need for vasopressin replacement. Certain drugs can inhibit renal water excretion through direct effects on the nephron, thus causing hyponatremia; these drugs include high-dose cyclophosphamide, vinblastine, cisplatinum, carbamazepine, and oxcarbazepine.

Cerebral Salt Wasting

Cerebral salt wasting appears to be the result of hypersecretion of atrial natriuretic peptide and is seen primarily with central nervous system disorders including brain tumors, head trauma, hydrocephalus, neurosurgery, cerebrovascular accidents, and brain death. Hyponatremia is accompanied by elevated urinary sodium excretion (often >150 mEq/L), excessive urine output, hypovolemia, normal or high uric acid, suppressed vasopressin, and elevated atrial natriuretic

Table 559-3 Genetic Mutations Associated with Hypoaldosteronism/Pseudohypoaldosteronism (Type IV Renal Tubular Acidosis)

GENE CHROMOSOME OMIM	PATHOPHYSIOLOGY	MUTATION–CLINICAL MANIFESTATIONS–OMIM–INHERITANCE
PRIMARY HYPOALDOSTERONISM		
CYP21A2—cytochrome P450, subfamily XXIA, polypeptide 2 6p21.3 613815	P450c21—steroid 21-hydroxylase that converts 17 α-hydroxyprogesterone to 11-deoxycortisol and progesterone to 11-deoxycorticosterone in the adrenal zona fasciculata	Loss-of-function mutations decrease synthesis of cortisol and aldosterone, the latter resulting in the salt-losing form of classical congenital adrenal hyperplasia, AR–201910
CYP11B2—cytochrome P450, subfamily XIB, polypeptide 2 8q21 124080	P450c11B2—aldosterone synthase/corticosterone methyoxidase types I and II expressed only in the zona glomerulosa; hydroxylates deoxycorticosterone at carbon-11 and corticosterone at carbon-18 and oxidizes 18-hydroxycorticosterone to aldosterone	Loss-of-function mutations associated with severe salt loss and volume depletion but not with abnormalities of genital formation or glucocorticoid synthesis AR (CMOI 203400; CMOII 610600)
PSEUDOHYPOALDOSTERONISM TYPE I		
NR3C2—nuclear receptor subfamily 3, group C, member 2 (MR-mineralocorticoid receptor), 4q31.1 600983	Ligand-activated nuclear transcription factor that transmits aldosterone-mediated control of gene expression by binding to the mineralocorticoid response element in the promoter region of the target gene	Loss-of-function mutations lead to mineralocorticoid resistance and pseudohypoaldosteronism type I, AD–177735
SCNN1A—sodium channel, non–voltage-gated, α-subunit 12p13.31 600228	Inactivating mutation of α-subunit of the epithelial sodium channel	Pseudohypoaldosteronism type I, AR–264350
SCNN1B—sodium channel, non–voltage-gated, β-subunit 16p12.2 600760	Inactivating mutation of β-subunit of the epithelial sodium channel	Pseudohypoaldosteronism type I, AR–264350
SCNN1G—sodium channel, non–voltage-gated, γ-subunit 16p12.2 600761	Inactivating mutation of γ-subunit of the epithelial sodium channel	Pseudohypoaldosteronism type I, AR–264350
PSEUDOHYPOALDOSTERONISM TYPE II		
WNK4—protein kinase, lysine-deficient 4 17q21.31 601844	Multifunctional serine-threonine protein kinase whose substrate is SLC12A3, the thiazide-sensitive sodium/chloride cotransporter (NCCT)—OMIM 600968—that also regulates lysosomal degradation of NCCT and endocytosis of the KCNJ1 potassium channel	Pseudohypoaldosteronism type IIB, AD–614491
WNK1—protein kinase, lysine-deficient 1 12p13.33 605232	Serine-threonine protein kinase that inactivates WNK4 by phosphorylating its kinase domain	Pseudohypoaldosteronism type IIC, AD–614492
KLH3—Kelch-like 3 5q31.2 605775	Adaptor protein within the ubiquitination sequence that links WNK1 and WNK4 to CUL3	Pseudohypoaldosteronism type IID, AD/AR–614495
CUL3—Cullin 3 2q36.2 603136	Scaffold protein that links to RING-box E3 ligase facilitating WNK4 ubiquitination and proteasomal destruction of WNK4	Pseudohypoaldosteronism type IIE, AD–614496

AD, autosomal dominant; AR, autosomal recessive; CMO, corticosterone methyloxidase; OMIM, Online Mendelian Inheritance in Man.

From Root AW: Disorders of aldosterone synthesis, secretion, and cellular function. Curr Opin Pediatr *26:480–486, 2014, Table 1, p. 483.*

peptide concentrations (>20 pmol/L). Thus, it is distinguished from SIADH, in which normal or decreased urine output, euvolemia, only modestly elevated urine sodium concentration, and an elevated vasopressin level occur. The distinction between cerebral salt wasting and SIADH is important because the treatment of the 2 disorders differs markedly. However, its existence has been questioned, because few patients with the suspected syndrome have documented hypovolemia and thus might truly have SIADH.

Runners' Hyponatremia

Excess fluid ingestion during long-distance running (e.g., marathon running) can result in severe hyponatremia from hypovolemia-induced activation of arginine vasopressin secretion coupled with excessive water ingestion and is correlated with weight gain, long racing time, and extremes of body mass index.

Pseudohyponatremia and Other Causes of Hyponatremia

Pseudohyponatremia can result from hypertriglyceridemia (see Chapter 55). Elevated lipid levels result in a relative decrease in serum water content. As electrolytes are dissolved in the aqueous phase of the serum, they appear low when expressed as a fraction of the total serum volume. As a fraction of serum water, however, electrolyte content is normal. Modern laboratory methods that measure sodium concentration directly, independent of sample volume, do not cause this anomaly. Factitious hyponatremia can result from obtaining a blood sample proximal to the site of intravenous hypotonic fluid infusion.

Hyponatremia is also associated with hyperglycemia, which causes the influx of water into the intravascular space. Serum sodium decreases by 1.6 mEq/L for every 100 mg/dL increment in blood glucose >100 mg/dL. Glucose is not ordinarily an osmotically active agent and does not stimulate vasopressin release, probably because it can equilibrate freely across plasma membranes. In the presence of insulin deficiency and hyperglycemia, however, glucose acts as an osmotic agent, presumably because its normal intracellular access to osmosensor sites is prevented. Under these circumstances, an osmotic gradient exists, stimulating vasopressin release.

TREATMENT

Patients with systemic dehydration and hypovolemia should be rehydrated with salt-containing fluids such as normal saline or lactated Ringer solution. Because of activation of the renin–angiotensin–aldosterone system, the administered sodium is avidly conserved, and water diuresis quickly ensues as volume is restored and vasopressin concentrations decrease. Under these conditions, caution must be taken to prevent a too-rapid correction of hyponatremia, which can

result in central pontine myelinolysis characterized by discrete regions of axonal demyelination and the potential for irreversible brain damage.

Hyponatremia from a decrease in effective plasma volume caused by cardiac, hepatic, renal, or pulmonary dysfunction is more difficult to reverse. The most effective therapy is the least easily achieved: treatment of the underlying systemic disorder. For example, patients weaned from positive pressure ventilation undergo a prompt water diuresis and resolution of hyponatremia as cardiac output is restored and vasopressin concentrations decrease. Vaptans represent a new class of small-molecule arginine vasopressin V2 receptor antagonists (aquaretics) useful for the treatment of hypervolemic hyponatremia associated with severe congestive heart failure and chronic liver failure. Although these agents successfully increase plasma sodium, they also lead to increased thirst and plasma vasopressin levels, which can limit their effectiveness.

Patients with hyponatremia from primary salt loss require supplementation with sodium chloride and fluids. Initially, intravenous replacement of urine volume with fluid containing sodium chloride, 150-450 mEq/L depending on the degree of salt loss, may be necessary; oral salt supplementation may be required subsequently. This treatment contrasts with that of SIADH, in which water restriction without sodium supplementation is the mainstay.

Emergency Treatment of Hyponatremia

The development of acute hyponatremia (onset <12 hr) or a serum sodium concentration <120 mEq/L may be associated with lethargy, psychosis, coma, or generalized seizures, especially in younger children. Acute hyponatremia can cause cell swelling and lead to neuronal dysfunction or to cerebral herniation. The emergency treatment of cerebral dysfunction resulting from acute hyponatremia includes water restriction and can require rapid correction with hypertonic 3% sodium chloride. If hypertonic saline treatment is undertaken, the serum sodium should be raised only high enough to cause an improvement in mental status, and in no case faster than 0.5 mEq/L/hr or 12 mEq/L/24 hr.

Treatment of Syndrome of Inappropriate Antidiuretic Hormone

Chronic SIADH is best treated by oral fluid restriction. With full antidiuresis (urine osmolality of 1,000 mOsm/kg), a normal daily obligate renal solute load of 500 mOsm/m^2 would be excreted in 500 mL/m^2 water. This, plus a daily nonrenal water loss of 500 mL/m^2, would require that oral fluid intake be limited to 1,000 mL/m^2/24 hr to avoid hyponatremia. In young children, this degree of fluid restriction might not provide adequate calories for growth. In this situation, the creation of nephrogenic diabetes insipidus using demeclocycline therapy may be indicated to allow sufficient fluid intake for normal growth. Urea has also been safely used to induce an osmotic diuresis in infants and children.

Treatment of Cerebral Salt Wasting

Treatment of patients with cerebral salt wasting consists of restoring intravascular volume with sodium chloride and water, as for the treatment of other causes of systemic dehydration. The underlying cause of the disorder, which is usually due to acute brain injury, should also be treated if possible. Treatment involves the ongoing replacement of urine sodium losses volume for volume.

Chapter 560

Hyperpituitarism, Tall Stature, and Overgrowth Syndromes

Omar Ali

HYPERPITUITARISM

Primary hypersecretion of pituitary hormones rarely occurs in the pediatric population and should be distinguished from **secondary hyperpituitarism,** which occurs in the setting of target hormone deficiencies resulting in decreased hormonal feedback, such as in hypogonadism, hypoadrenalism, or hypothyroidism. In secondary hyperpituitarism, chronic pituitary hypersecretion occurs in response to target hormone deficiencies and leads to pituitary hyperplasia, which can enlarge and erode the sella and, on rare occasions, increase intracranial pressure. Such enlargements should not be confused with primary pituitary tumors; they disappear when the underlying hormone deficiency is treated. The elevated pituitary hormone levels readily suppress to normal following replacement of end-organ hormones. Pituitary hyperplasia can also occur in response to stimulation by ectopic production of releasing hormones such as that seen occasionally in patients with Cushing syndrome secondary to corticotropin-releasing hormone excess or in children with acromegaly secondary to growth hormone–releasing hormone (GHRH) produced by a variety of systemic tumors.

Primary hypersecretion of pituitary hormones by adenoma is uncommon in childhood. The most commonly diagnosed adenoma during childhood is prolactinoma, followed by corticotropinoma, and then somatotropinoma, which secrete prolactin, corticotropin, and growth hormone, respectively. There are a handful of case reports of thyrotropinoma in children and adolescents. There are no pediatric reports of gonadotropinoma, but hypothalamic hamartomas that secrete excess gonadotropin-releasing hormone are responsible for a significant proportion of cases of precocious puberty.

The monoclonal nature of most pituitary adenomas implies that most originate from a clonal event in a single cell. It is suspected that some pituitary tumors result from stimulation with hypothalamic-releasing hormones and in other instances, as in McCune-Albright syndrome (MAS), the tumor is caused by activating mutations of the *GNAS1* gene that codes for the α subunit of $G_s\alpha$, a guanine nucleotide-binding protein. The clinical presentation typically depends on the pituitary hormone that is hypersecreted. Disruptions of growth regulation and/or sexual maturation are common, as a result of either hormone hypersecretion or local compression by the tumor. MAS also features polyostotic fibrous dysplasia of bone and café-au-lait spots in a distinct distribution.

TALL STATURE

The normal distribution of height predicts that 2.3% of the population will be taller than 2 SD (97.7%) above the mean. The social acceptability and even desirability of tallness (heightism) makes tall stature an uncommon complaint in clinical practice. It is exceptionally unusual for boys and men to seek medical attention regarding excessive height. Girls (or their parents) were historically more likely to approach a physician with concern about tall stature, but even in girls this complaint has become less frequent as tallness has become more acceptable and socially desirable in adult women. Concern about side effects of estrogen treatment and reports of dissatisfaction among adult women subjected to this treatment have also led to a decline in estrogen use.

Table 560-1 Differential Diagnosis of Tall Stature and Overgrowth Syndromes

FETAL OVERGROWTH
Maternal diabetes mellitus
Cerebral gigantism (Sotos syndrome)
Weaver syndrome
Beckwith-Wiedemann syndrome
Other IGF-2 excess syndromes
POSTNATAL OVERGROWTH LEADING TO CHILDHOOD TALL STATURE
Nonendocrine Causes
Familial (constitutional) tall stature
Exogenous obesity
Cerebral gigantism (Sotos syndrome)
Weaver syndrome
Marfan syndrome
Fragile X syndrome
Beckwith-Wiedemann syndrome
Klinefelter syndrome (XXY)
SHOX excess syndromes
Homocystinuria
XYY
Endocrine Causes
Excess GH secretion (pituitary gigantism)
McCune-Albright syndrome or MEN associated with excess GH secretion
Precocious puberty
Hyperthyroidism
POSTNATAL OVERGROWTH LEADING TO ADULT TALL STATURE
Familial (constitutional) tall stature
Marfan syndrome
Klinefelter syndrome (XXY)
XYY
Androgen or estrogen deficiency or estrogen resistance
Androgen insensitivity syndrome (testicular feminization)
ACTH or cortisol deficiency or resistance
Excess GH secretion (pituitary gigantism)

ACTH, adrenocorticotropic hormone; GH, growth hormone; IGF, insulin-like growth factor; MEN, multiple endocrine neoplasia.

Differential Diagnosis of Tall Stature

Unusual tall stature can have different causes in each age group. Table 560-1 lists the causes of tall stature in childhood and adolescence. Figure 560-1 shows an approach to diagnosis.

Overgrowth in the Fetus and Neonate

Maternal diabetes is the most common cause of infants large for gestational age. Even in the absence of clinical symptoms or a family history, the birth of a large-for-gestational-age infant should lead to evaluation for maternal (or gestational) diabetes.

A group of disorders associated with excessive somatic growth and growth of specific organs has been described and is collectively referred to as overgrowth syndromes. These disorders appear to be caused in many cases by excess production and availability of insulin-like growth factor 2 (IGF-2) encoded by the gene *Igf2.* The best described of these syndromes is the **Beckwith-Wiedemann syndrome** (BWS), which is an overgrowth malformation syndrome that occurs with an incidence of 1 : 14,000 births, equal in males and females. Approximately 15% of cases are familial, while the rest appear to be sporadic. Most cases of BWS are caused by deregulation of imprinted genes within the chromosome 11p15.5 region. Genetic disruptions affecting this region include gene duplication, loss of heterozygosity, and relaxation or loss of imprinting. The "imprinted" genes involved in BWS and associated childhood tumors include, in addition to *Igf2,* the gene *H19,* which is involved in *Igf2* suppression, as well as *WT-1* (the Wilms tumor gene), cyclin-dependent kinase inhibitor 1C (CDKN1C), potassium channel voltage-gated KQT-like subfamily member 1 (KCNQ1), and KCNQ1-overlapping transcript 1 (KCNQ1OT1, or long QT intronic transcript 1, LIT1).

Affected infants characteristically have macrosomia including macroglossia, hepatosplenomegaly, nephromegaly, and omphalocele. They also have hypoglycemia secondary to hyperinsulinemia as a result of pancreatic β-cell hyperplasia. Children with BWS are predisposed to a specific subset of childhood neoplasms (embryonal tumors), including Wilms tumor, hepatoblastoma, neuroblastoma, and adrenocortical carcinoma. Management focuses on omphalocele, airway issues (a result of macroglossia), and neonatal hypoglycemia. Cancer risk is high until 8 yr of age, and regular surveillance with abdominal ultrasound and measurement of α-fetoprotein is recommended every 3 mo until age 8 yr. Thereafter, renal ultrasound is recommended every 1-2 yr as medullary sponge kidney and nephrocalcinosis may develop later.

Mutations in *GPC3*, a glypican gene (which codes for an IGF-2-neutralizing membrane receptor), cause the related Simpson-Golabi-Behmel overgrowth syndrome. Other syndromic causes of fetal overgrowth include Costello syndrome, Weaver syndrome, Sotos syndrome, and Perlman syndrome.

Overgrowth in Childhood or Adolescence

Normal variant, familial, or constitutional tall stature is by far the most common cause of tall stature. Almost invariably, a family history of tall stature can be obtained, and no organic pathology is present. The child is often taller than the child's peers throughout childhood and enjoys excellent health. The parent of the constitutionally tall adolescent might reflect unhappily upon his or her own adolescence as a tall teenager. There are no abnormalities in the physical examination, and the laboratory studies, if obtained, are negative.

Exogenous obesity is a common condition in adolescence and may be associated with rapid linear growth and early onset of puberty. Bone age is accelerated leading to relative tall stature in childhood but adult height is typically normal.

Klinefelter syndrome (XXY syndrome) is a relatively common (1 in 500-1,000 live male births) abnormality associated with tall stature, learning disabilities (including requirement for speech therapy), gynecomastia, and decreased upper body:lower body segment ratio. Affected boys can have hypotonia, clinodactyly, and hypertelorism. The testes are invariably small, although androgen production by Leydig cells is often in the low-normal range. Spermatogenesis and Sertoli cell function are defective, and infertility results. Other genital abnormalities including relatively small phallus, hypospadias, and cryptorchidism may be present.

XYY syndrome is associated with tall stature, problems in motor and language development, and possible antisocial behavior.

Marfan syndrome is an autosomal dominant connective tissue disorder consisting of tall stature, arachnodactyly, thin extremities, increased arm span, and decreased upper body:lower body segment ratio (see Chapter 702). Additional abnormalities include ocular abnormalities (e.g., lens subluxation), hypotonia, kyphoscoliosis, cardiac valvular deformities, and aortic root dilation.

Homocystinuria is an autosomal recessive inborn error of amino acid metabolism, caused by a deficiency of the enzyme cystathionine synthetase. It is characterized by intellectual disability when untreated, and many of its clinical features resemble Marfan syndrome, particularly ocular manifestations (see Chapter 85).

SOTOS SYNDROME (CEREBRAL GIGANTISM)

Children with cerebral gigantism (also known as Sotos syndrome) are above the 90th percentile for both length and weight at birth; they can also have macrocrania at that time. Most cases of Sotos syndrome are caused by mutations in the *NSD1* (nuclear receptor SET domain-containing protein 1) gene, but in the Japanese population most cases are attributable to microdeletions of the 5q35 region that includes this gene. Inheritance is autosomal dominant, but 95% of cases are a result of new mutations. Incidence is estimated to be approximately 1 in 14,000 live births. The *NSD1* gene is thought to play a role in epigenetic regulation, but the mechanisms by which mutations lead to the features of Sotos syndrome are not clear at this time.

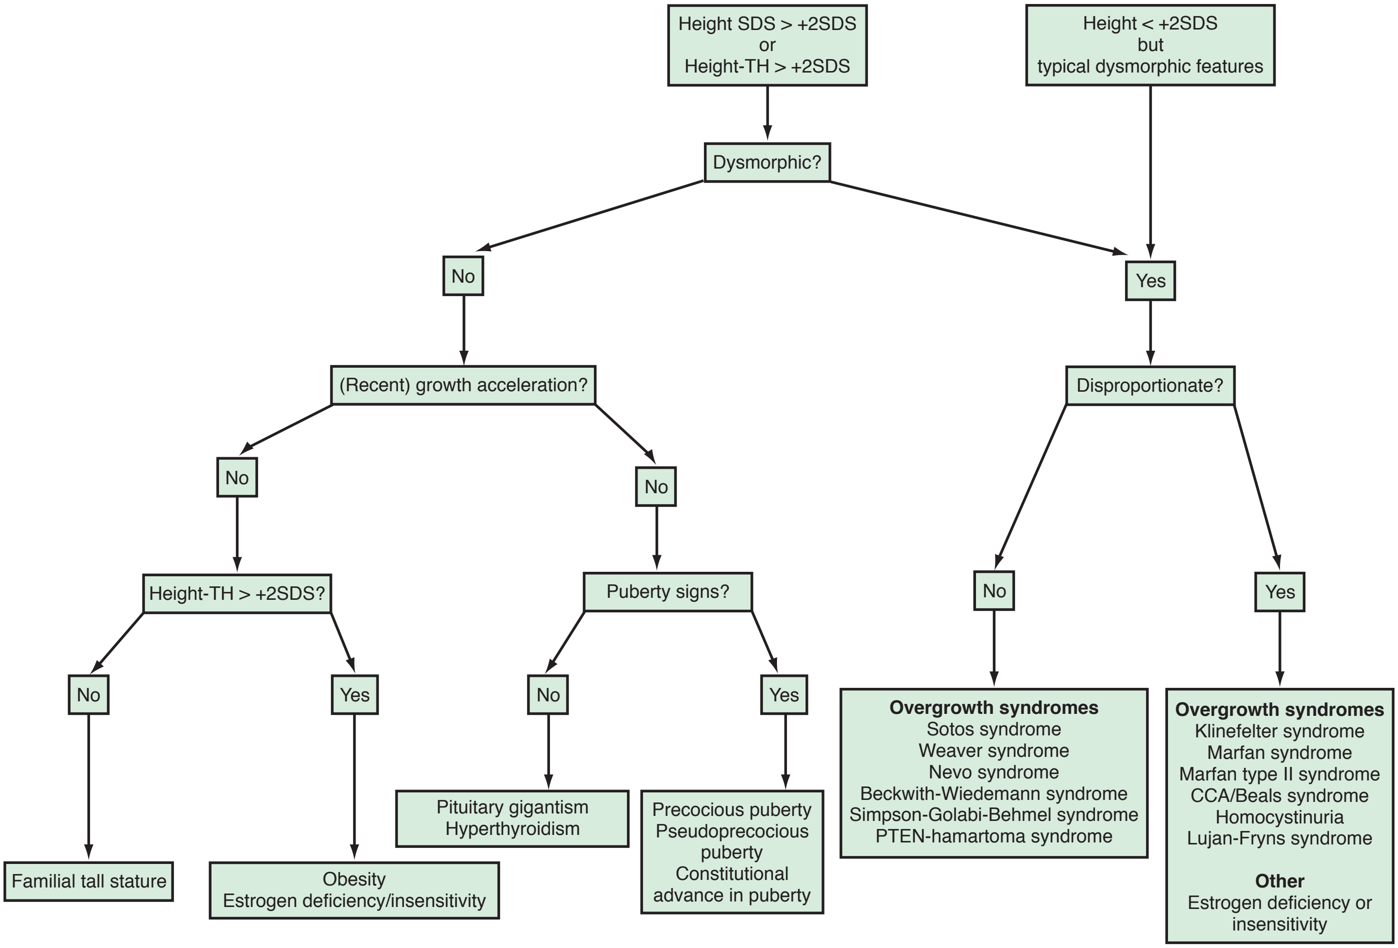

Figure 560-1 Diagnostic flow chart for the differential diagnosis of tall stature and overgrowth syndromes. Height-TH, current height percentile >2 SDS from target height percentile, the latter based on midparental height calculation; SDS, standard deviation score. *(From Neylon OM, Werther GA, Sabin MA: Overgrowth syndromes.* Curr Opin Pediatr *24:505–511, 2012, Fig. 1, p. 507.)*

Although it is characterized by rapid growth, there is no evidence that Sotos syndrome is caused by endocrine dysregulation. A hypothalamic defect has been suggested as a cause, but none has been demonstrated functionally or at necropsy. Growth is markedly rapid; by 1 yr of age, affected infants are taller than the 97th percentile in height. Accelerated growth continues for the 1st 4-5 yr and then returns to a normal rate (see Fig. 560-1). Puberty usually occurs at the expected time but may occur slightly early. Adult height is usually in the upper normal range.

Clinically the syndrome is characterized by a large (macrocephaly) dolichocephalic head, prominent forehead and jaw, hypertelorism, antimongoloid slant of the palpebral fissures, high-arched palate, and large hands and feet with thickened subcutaneous tissue. Clumsiness and awkward gait are also noted, and affected children have great difficulty in sports, in learning to ride a bicycle, and in other tasks requiring coordination. Some degree of developmental disability affects most patients; in some affected children perceptual deficiencies may predominate. Many different types of nonfebrile seizures have been reported and up to 25% of patients with Sotos syndrome have seizures at some point in their life. Affected patients may be at somewhat increased risk for neoplasms, including neuroblastoma, hepatoblastoma, and leukemia, with a lifetime risk of between 2% and 4%. Osseous maturation is usually compatible with the patient's height, although advanced bone age has been reported. Scoliosis develops in up to 30% of cases, usually starting in school-age children. Growth hormone (GH), IGF-1, and other endocrine studies are usually normal; there is no distinctive laboratory or radiologic marker for the syndrome. Abnormal electroencephalograms are common; imaging studies often reveal an enlarged ventricular system, but intracranial pressure is normal. Genetic testing for *NSD1* mutations (or fluorescence in situ hybridization for 5q35 microdeletions in Japanese patients) is available and should be routinely used. Management is symptomatic and includes paying special attention to developmental and behavioral problems (which tend to improve with age), scoliosis, and seizure disorder. No specific treatment is needed for the overgrowth itself. There is no consensus on the need for cancer surveillance at this time.

Table 560-2 notes additional features of overgrowth syndromes.

Hyperthyroidism in adolescents is associated with rapid growth but normal final adult height. It is almost always caused by Graves disease and is much more common in girls (see Chapter 568).

Precocious puberty, whether mediated centrally (increased gonadotropin secretion) or peripherally (increased secretion of androgens or estrogens, or both), results in accelerated linear growth during childhood, mimicking the pubertal growth spurt. Because skeletal maturation is also advanced, adult height is often compromised. Chapter 562 discusses the diagnostic evaluation and management of precocious puberty.

Although **delayed puberty** may be associated with short stature in childhood, as with constitutional delay, failure to eventually enter puberty and complete sexual maturation can result in sustained growth during adult life, with ultimate tall stature. The report of tall stature with open epiphyses resulting from a mutation of the estrogen receptor in a man with normal male sexual maturation underscores the fundamental role of estrogen in promoting epiphyseal fusion and termination of normal skeletal growth. Aromatase deficiency leads to tall stature through similar pathways.

Table 560-2 Genetic Overgrowth Syndromes

GENETIC SYNDROMES	CLINICAL FEATURES	INCIDENCE OF MALIGNANCY (%)	ETIOLOGY	INVESTIGATIONS AND MANAGEMENT
Beckwith-Wiedemann syndrome*	Hypoglycemia, large tongue, ear pits, omphalocele or umbilical hernia, hemihyperplasia	~7.5		US heart, kidneys Chromosomes 11p FISH and/ or MLPA, methylation studies Tumor surveillance justified
Perlman syndrome*	Macrosomia, unusual facies Nephroblastosis		Rare autosomal recessive	US brain (ACC), heart (coarctation), kidneys
Simpson-Golabi-Behmel syndrome*	Coarse facial features, macroglossia, central groove lower lip, supernumerary nipples	~7.5	X-linked recessive (glypican-3 mutations)	US heart, kidney X-ray spine (vertebral segmentation anomaly) Tumor surveillance justified
Sotos syndrome	Facial gestalt (long, thin face, broad forehead) Feeding difficulties Hypotonia	~4	Usually de novo dominant *NSD1* deletion or mutation Rare familial cases	US heart, kidneys Monitor development
PTEN-hamartoma syndrome (Bannayan-Ruvalcaba-Riley)	Macrocephaly (>97th percentile) often progressive from birth, hypotonia, pigmented skin, penile macules, lipomas	Uncertain	Sporadic or autosomal dominant *PTEN* mutation	US head, heart, and kidney Monitor development
Weaver syndrome	Broad forehead, hypertelorism, small chin, long philtrum, camptodactyly, fetal finger pads	~5-6	Rare, unknown	US heart, brain, kidney
Marfan syndrome type I	Facial gestalt, arachnodactyly, scoliosis, pectus carinatum or excavatum, aortic root dilation, lens dislocation		Autosomal dominant fibrillin-1 *(FBN1)*	Eye examination and follow-up Heart US and cardiology follow-up Monitor scoliosis
Marfan syndrome type II or Loeys-Dietz syndrome	Marfan-like habitus, aortic root dilation, aortic dissection, vasculopathy		Autosomal dominant, TGF-β pathway anomaly *TGFBR1* and *TGFBR2* genes	Eye examination usually normal Heart US and follow-up Monitor scoliosis
Beals syndrome	Congenital distal arthrogryposis Crumpled ears		Autosomal dominant fibrillin 2 *(FBN2)*	Eye examination and heart US usually normal
Homocystinuria	Marfan-like habitus Developmental delay Lens dislocation		Autosomal recessive Cystathionine β-synthase (CBS) mutation	Urine metabolic screen Eye examination Monitor development
Lujan syndrome	Marfanoid habitus plus intellectual disability		X-linked recessive *MED12* gene	Eye examination usually normal Heart US usually normal
Sex chromosome aneuploidy Klinefelter 47XXY, 47XYY, 47XXX	Tall stature, small testes, gynecomastia Tall stature, ± learning disability			Androgen replacement from puberty in Klinefelter syndrome Monitor development
Autosomal anomaly Tetrasomy 12p mosaicism,* pat 11pdup, 4pdub, 22q13del, 15q26-qter dup	Congenital overgrowth or childhood tall stature with intellectual disability			Monitor development

*Overgrowth often presenting at birth.

ACC, agenesis of the corpus callosum; FISH, fluorescence in situ hybridization; MLPA, multiple ligation probe amplification; PTEN, phosphatase and tensin homolog; TGF, transforming growth factor; TGFBR, transforming growth factor β receptor; US, ultrasound.

From Verge CF, Mowat D: Overgrowth, Arch Dis Child *95:458–463, 2010.*

The purpose of the diagnostic evaluation of tall stature is to distinguish the commonly occurring, normal variant, constitutional variety from the rare pathologic conditions. Often, when the history suggests familial tall stature and the physical examination is entirely normal, no laboratory tests are indicated. It is valuable to obtain a bone age radiograph to be able to predict adult height, which serves as a basis for discussions with the family and for management decisions. If the history suggests any of the aforementioned disorders or the physical examination reveals abnormalities, additional laboratory tests should be obtained. IGF-1 and IGF-binding protein-3 (IGFBP-3) are excellent screening tests for GH excess and can be verified with a glucose suppression test. Laboratory evidence of GH excess mandates MRI evaluation of the pituitary. Chromosome analysis is useful in boys, especially when the ratio of upper to lower body segment is decreased or when developmental disability is present, to rule out Klinefelter syndrome. If Marfan syndrome or homocystinuria is suspected from the physical examination, referral to a cardiologist and an ophthalmologist should be made. Thyroid function tests are

useful to diagnose or rule out hyperthyroidism when this disorder is suspected.

Treatment of Normal Variant Tall Stature

Reassurance of the family and the patients is the key to the management of normal variant tall stature. The use of the bone age to predict adult height might provide some comfort for them, as will general supportive discussions on the social acceptability of this condition. Although treatment is possible for girls and boys with excessive growth, its use should be restricted to patients with predicted adult height >3-4 SD above the mean (79 inches or 200 cm in boys, 73 inches or 185 cm in girls) and evidence of significant psychosocial impairment.

Sex steroids have been used in the treatment of tall stature and are designed to accelerate puberty and to promote epiphyseal fusion; these are therefore of little benefit when given in late puberty. The lack of extensive experience with this form of therapy and the risks of estrogen or androgen treatment for tall stature should be carefully weighed and discussed with the family and treatment should be discouraged except in the most extreme cases. Detailed discussion with the child at the child's level is also advisable as up to 40% of those who underwent such treatments are dissatisfied as adults and feel they were not sufficiently consulted about this course of action. Therapy is initiated ideally before puberty or in early puberty. In boys, treatment should begin before the bone age reaches 14 yr. In the extremely rare instances where treatment is desired, testosterone enanthate is used at a dose of 500 mg intramuscularly every 2 wk for 6 mo. In girls, oral estrogens in various doses have been used to reduce the predicted height, but average height reduction may be only 1.1-2.4 cm. Therapy must begin before the bone age has reached 12 yr. In the rare case where treatment is advised, oral ethinyl estradiol at a dose of 0.15-0.5 mg/day until cessation of growth occurs has been used. Short-term side effects have included benign breast disease, cholelithiasis, hypertension, menstrual irregularities, weight gain, nausea, limb pain, galactorrhea, and thrombosis. Reduced fertility later in life may be a potential long-term complication.

EXCESS GROWTH HORMONE SECRETION AND PITUITARY GIGANTISM

In young persons with open epiphyses, overproduction of GH results in **gigantism;** in persons with closed epiphyses, the result is **acromegaly.** Often some acromegalic features are seen with gigantism, even in children and adolescents. After closure of the epiphyses, the acromegalic features become more prominent.

Gigantism is rare, with only several hundred reported cases to date. Most cases are sporadic and are caused by pituitary adenomas or excessive GHRH secretion by the hypothalamus (and, rarely, by tumors in other parts of the body). **Syndromes associated with pituitary GH excess include** MAS, which is caused by mutations resulting in constitutively activated G-proteins, and can include somatotrophic tumors and excess GH secretion. Approximately 20% of patients with gigantism have MAS (commonly consisting of a triad of precocious puberty, café-au-lait spots, and fibrous dysplasia) and 20% of patients with MAS have some degree of GH hypersecretion. GH-secreting tumors are seen in approximately 60% of patients with **multiple endocrine neoplasia type 1,** but almost all these tumors develop in adult life and cause acromegaly rather than pituitary gigantism. Increased GH secretion and GH-secreting adenomas may also be seen in **neurofibromatosis, tuberous sclerosis**, and **Carney complex**.

The cardinal clinical feature of gigantism is longitudinal growth acceleration secondary to GH excess. The usual manifestations consist of coarse facial features and enlarging hands and feet. In young children, rapid growth of the head can precede linear growth. Some patients have behavioral and visual problems. In most recorded cases, the abnormal growth became evident at puberty, but the condition has been established as early as the newborn period in 1 child and at 21 mo of age in another. Giants have rarely been reported to grow to a height of over 8 ft. In some cases the patient may present with local effects of the pituitary tumor (headache, visual field defects, and other pituitary hormone deficiencies) as the main complaint, and there is at least 1 report of a patient presenting with diabetic ketoacidosis induced by GH excess. The presentation of gigantism is usually dramatic, unlike the insidious onset of acromegaly in adults.

Approximately 50% of the pituitary adenomas that cause gigantism also exhibit hyperprolactinemia because they secrete both GH and prolactin. This is because mammosomatotrophs are the most common type of GH-secreting cells involved in childhood gigantism. GH-secreting tumors of the pituitary are typically eosinophilic or chromophobic adenomas. Adenomas can compromise other anterior pituitary function through growth or cystic degeneration. Secretion of gonadotropins, thyrotropin, or corticotropin may be impaired. Delayed sexual maturation or hypogonadism can occur. When GH hypersecretion is accompanied by gonadotropin deficiency, accelerated linear growth can persist for decades. In some cases, the tumor spreads outside the sella, invading the sphenoid bone, optic nerves, and brain. GH-secreting tumors in pediatric patients are more likely to be locally invasive or aggressive than are those in adults.

Acromegalic features consist chiefly of enlargement of the distal parts of the body, but manifestations of abnormal growth involve all portions. The circumference of the skull increases, the nose becomes broad, and the tongue is often enlarged, with coarsening of the facial features. The mandible grows excessively, and the teeth become separated. Visual field defects and neurologic abnormalities are common; signs of increased intracranial pressure appear later. The fingers and toes grow chiefly in thickness. There may be dorsal kyphosis. Fatigue and lassitude are early symptoms. GH levels are elevated and occasionally exceed 100 ng/mL. There is usually no suppression of GH levels by the hyperglycemia of a glucose tolerance test and IGF-1 and IGFBP-3 levels are consistently elevated in acromegaly and pituitary gigantism.

Diagnosis

Most children with tall stature do not have pituitary gigantism and other etiologies of rapid linear growth such as genetic tall stature, precocious puberty, and hyperthyroidism should be carefully excluded. Coexisting findings (e.g., dysmorphic facial features, neurocognitive problems, hemihypertrophy) may suggest syndromic or chromosomal causes of tall stature, such as Sotos, Weaver, Klinefelter, or XYY syndrome. GH hypersecretion can be screened for by testing IGF-1 and IGFBP-3 levels. An excellent linear dose–response correlation between serum IGF-1 levels and 24 hr mean GH secretion has been demonstrated. An elevated IGF-1 level in a patient with appropriate clinical suspicion usually indicates GH excess. Potential confusion can arise in the evaluation of normal adolescents because significantly higher IGF-1 levels occur during puberty than in adulthood, so the IGF-1 level must be age and gender matched. Serum IGFBP-3 levels are also sensitive markers of GH elevations and will be elevated in almost all cases. If IGF-1 and/or IGFBP-3 levels are elevated, then the next step is to test for GH excess by doing an oral glucose-suppression test. The gold standard for the diagnosis of GH excess in adults is the failure to suppress serum GH levels to <1 ng/dL at any time during a 2 hr oral glucose tolerance test with 1.75 g/kg oral glucose challenge (maximum: 75 g). GH levels may not be suppressed to this level in normal adolescents and a cutoff of 5 ng/mL may be more appropriate in this age group. If laboratory findings suggest GH excess, the presence of a pituitary adenoma should be confirmed by MRI of the brain. In rare cases, a pituitary mass is not identified. This might be from an occult pituitary microadenoma or ectopic production of GHRH or GH. CT is acceptable when MRI is unavailable.

Treatment

The goals of therapy are to remove or shrink the pituitary mass, to restore GH and secretory patterns to normal, to restore IGF-1 and IGFBP-3 levels to normal, to retain the normal pituitary secretion of other hormones, and to prevent recurrence of disease.

For well-circumscribed pituitary adenomas, transsphenoidal surgery is the treatment of choice and may be curative. The tumor should be removed completely. The likelihood of surgical cure depends greatly on the surgeon's expertise as well as on the size and extension of the mass. Intraoperative GH measurements can improve the results of tumor resection. Transsphenoidal surgery to resect the tumors is as

safe in children as in adults. At times, a transcranial approach might be necessary. The primary goal of treatment is to normalize GH and IGF-1 levels. GH levels (<1 ng/mL within 2 hr after a glucose load) and serum IGF-1 levels (age-adjusted normal range) are the best tests to define a biochemical cure.

If GH secretion and IGF-1 levels are not normalized by surgery, the options include pituitary irradiation and medical therapy. Further growth of the tumor is prevented by irradiation in >99% of patients. The main disadvantage is the delayed efficacy in decreasing GH levels. GH is reduced by approximately 50% from the initial concentration by 2 yr, by 75% by 5 yr, and approaches 90% by 15 yr. Multiple pituitary hormone deficiency is a predictable outcome, occurring in 40-50% of patients 10 yr after irradiation.

Surgery fails to cure a significant number of patients and radiotherapy may not work fast enough, so medical therapy has an important role in treating patients with GH excess. Treatment is effective and well tolerated with long-acting somatostatin analogs and dopamine agonists, as well as by novel GH antagonists.

The **somatostatin analogs** are highly effective in the treatment of patients with GH excess. Octreotide suppresses GH to <2.5 ng/mL in 65% of patients with acromegaly and normalizes IGF-1 levels in 70%. The effects of octreotide are well sustained over time. Tumor shrinkage also occurs with octreotide but is generally modest. Consistent GH suppression can be obtained with a continuous SC pump infusion of octreotide or with long-acting formulations, including long-acting octreotide and lanreotide. These produce consistent GH and IGF-1 suppression in acromegalic patients with once-monthly or biweekly IM depot injections. These sustained-release preparations have not been formally tested in children. Octreotide injection in the pediatric population has been used at doses of 1-40 µg/kg/24 hr. In adults the long-acting form is used in a dose of 10-40 mg every mo, but no pediatric dose range has been established.

For patients with both GH and prolactin oversecretion, dopamine agonists, such as **bromocriptine and cabergoline,** which bind to pituitary dopamine type 2 receptors and may also suppress GH secretion, should be considered. Prolactin levels are often adequately suppressed, but GH levels and IGF-1 levels are rarely normalized with this treatment modality alone. Tumor shrinkage occurs in a minority of patients. The effectiveness of these agents may be additive to that of octreotide. Cabergoline therapy at doses of 0.25-4.0 mg/wk (given 1-2 times per wk) has been used in adults with acromegaly, and because of its less-frequent dosing and lower incidence of side effects as compared to bromocriptine, this is now considered the dopamine agonist of choice in both adults and children. Side effects can include nausea, vomiting, abdominal pain, arrhythmias, nasal stuffiness, orthostatic hypotension, sleep disturbances, and fatigue.

Pegvisomant is a GH-receptor antagonist that competes with endogenous GH for binding to the GH receptor. It effectively suppresses GH and IGF-1 levels in patients with acromegaly caused by pituitary tumors as well as ectopic GHRH hypersecretion. Normalization of IGF-1 levels occurs in up to 90% of patients treated daily with this drug for 3 mo or longer. The adult dosage is 10-40 mg via subcutaneous injection once daily, although twice-weekly protocols have also been reported as highly successful. IGF-1 levels and hepatic enzymes must be monitored. Combined therapy with somatostatin analogs and weekly pegvisomant injections also is effective. Pediatric experience is limited, but case reports indicate that it can successfully suppress IGF-1 levels when used in doses of 10-30 mg/day.

HYPERSECRETION OF OTHER PITUITARY HORMONES

Prolactinoma

Prolactin-secreting pituitary adenomas are the most common pituitary tumors in adolescents. With the advent of MRI, more of these tumors, particularly microadenomas (<1 cm in diameter), are being detected. The most common presenting manifestations are headache, primary or secondary amenorrhea, and galactorrhea. The disorder affects more than twice as many girls as boys; most patients have undergone normal puberty before becoming symptomatic. Only a few have delayed puberty. In some kindreds with type I multiple endocrine neoplasia, prolactinomas are the presenting feature during adolescence.

Prolactin levels may be elevated mildly (40-50 ng/mL) or markedly (10,000-15,000 ng/mL). Most prolactinomas in children are large (macroadenomas), cause the sella to enlarge, and in some cases cause visual field defects. Approximately 30% of patients with macroadenomas develop other pituitary hormone deficiencies, particularly GH deficiency. Alternatively, prolactin-secreting adenomas might also stain for and secrete excess GH and/or thyroid-stimulating hormone.

Prolactinomas should not be confused with the hyperprolactinemia and pituitary hyperplasia that can occur in patients with **primary hypothyroidism**, which is readily treated with thyroid hormone (see Chapter 565). Moderate elevations (<200 ng/mL) of prolactin are also associated with a variety of **medications** (antipsychotics, metoclopramide, phenothiazines, verapamil), with pituitary stalk dysfunction such as can occur with craniopharyngioma, with chronic stress (rarely >40 ng/mL), and with nipple stimulation.

In some cases, extreme hyperprolactinemia is associated with a "hook effect" that leads to factitiously low values on blood tests. In cases where clinical features are compatible with hyperprolactinemia, serial dilution of the lab specimen should be done to rule out this kind of measurement error. On the other hand, patients may have factitiously elevated prolactin levels on immunoassay as a result of the presence of prolactin polymers and dimers (macroprolactinemia). In cases where an elevated prolactin is detected in an asymptomatic patient, unnecessary diagnostic work-up and treatment can be avoided by performing polyethylene glycol precipitation to exclude the presence of macroprolactinemia, which is clinically benign.

In most patients where the hyperprolactinemia is secondary to an adenoma, it can be effectively treated with dopamine agonists. Treatment leads to lowering of prolactin levels and tumor shrinkage in the vast majority of patients. Because of its greater efficacy and lower incidence of side effects, cabergoline is considered the drug of choice for treatment of hyperprolactinemia in doses ranging from 0.125-1.0 mg twice weekly. Higher doses may be needed in some patients but carry the risk of inducing cardiac valvular abnormalities and should be carefully monitored.

When dopamine agonist treatment has been unsuccessful in lowering the serum prolactin concentration or the size of the adenoma, and when symptoms or signs attributable to hyperprolactinemia or adenoma size persist during treatment, transsphenoidal surgery should be considered.

Corticotropinoma

Corticotropinoma is very rare in children, and its peak occurrence is at age 14 yr. **Cushing disease** refers specifically to an adrenocorticotropic hormone–producing pituitary adenoma that stimulates excess cortisol production and secretion. It is more common than primary adrenal causes of Cushing syndrome, except in younger children (younger than 5 yr of age), in whom adrenal carcinomas and adrenal activating mutations of MAS are rare but dominant causes of the syndrome. Adenomas causing Cushing disease are almost always microadenomas with a diameter of <5 mm and are significantly smaller than all other types of adenomas at presentation. The most sensitive indicator of excess glucocorticoid secretion in children is growth failure, which generally precedes other manifestations. Patients develop weight gain that tends to be centripetal rather than generalized. Pubertal arrest, hypertension, large purplish striae, fatigue, and depression are also common. In prepubertal children, males are more frequently affected than females.

Midnight salivary cortisol measurements can be used as a screening test for cortisol excess, but confirmation requires at least 1 additional test (either 24 hr urinary free cortisol or an overnight dexamethasone suppression test). Location of the microadenoma is usually determined by MRI, and bilateral inferior petrosal sinus sampling may be needed in difficult cases. Transsphenoidal surgery is the treatment of choice for Cushing disease in children. Initial remission rates of 70-98% of patients and long-term success rates of 50-98% are reported. Residual transient hypoadrenalism is often observed after surgery, lasting as

long as 30 mo. Pituitary radiotherapy is used if cortisol levels remain elevated and/or adrenocorticotropic hormone levels continue to be detectable. Successful treatment may not correct the height deficit, and GH deficiency may be present after treatment and should be treated as required.

Chapter 561

Physiology of Puberty

Luigi R. Garibaldi and Wassim Chemaitilly

Between early childhood and approximately 8-9 yr of age (prepubertal stage), the hypothalamic-pituitary-gonadal axis is dormant, as reflected by undetectable serum concentrations of luteinizing hormone (LH) and sex hormones (estradiol in girls, testosterone in boys). One to 3 yr before the onset of clinically evident puberty, low serum levels of LH during sleep become demonstrable. This sleep-entrained LH secretion occurs in a pulsatile fashion and reflects endogenous episodic discharge of hypothalamic gonadotropin-releasing hormone (GnRH). Nocturnal pulses of LH continue to increase in amplitude and, to a lesser extent, in frequency as clinical puberty approaches. This pulsatile secretion of gonadotropins is responsible for enlargement and maturation of the gonads and the secretion of sex hormones. The appearance of the secondary sex characteristics in early puberty is the visible culmination of the sustained, active interaction occurring among hypothalamus, pituitary, and gonads in the peripubertal period. By midpuberty, LH pulses become evident even during the daytime and occur at approximately 90-120 min intervals. A second critical event occurs in middle or late adolescence in girls in whom cyclicity and ovulation occur. A positive feedback mechanism develops whereby increasing levels of estrogen in midcycle cause a distinct increase of LH.

The increasing secretion of hypothalamic GnRH in a pulsatile fashion thus underlies the onset of pubertal development. The resulting "GnRH pulse generator" is regulated by multiple neuropeptides, including glutamic acid, kisspeptin, and neurokinin-B (stimulatory) and γ-aminobutyric acid, preproenkephalin, and dynorphin (inhibitory). GnRH secretion is also regulated by factors produced by the glial cells, such as transforming growth factor α. Loss-of-function mutations of the *KISS1 R*—also known as *GPR54*—gene (the gene encoding a G-protein–coupled receptor whose ligand is kisspeptin) cause an autosomal recessive form of hypogonadotropic hypogonadism, whereas gain-of-function mutations of the gene are associated with precocious puberty. Increased transforming growth factor α signaling is associated with the occurrence of central precocious puberty in patients with hypothalamic hamartoma.

The interpretation of the hormonal changes of puberty is complex. Issues in interpreting LH and follicle-stimulating hormone measurements include the presence of multiple gonadotropin isoforms, immunoassay-related variability, and problems inherent to their pulsatile secretion, which mandates serial sampling in plasma. In addition, important sex differences exist in the maturation of the hypothalamus and pituitary gland, and serum LH concentrations tend to increase earlier in the course of the pubertal process in boys than in girls. Adrenocortical androgens also have a role in sexual maturation. Serum levels of dehydroepiandrosterone (DHEA) and its sulfate (DHEAS) begin to increase at approximately 6-8 yr of age, before any increase in LH or sex hormones and before the earliest physical changes of puberty are apparent; this process is called *adrenarche*. DHEAS is the most abundant adrenal C-19 steroid in the blood, and its serum concentration remains fairly stable over 24 hr. A single measurement of this hormone is commonly used as a marker of adrenal androgen secretion. Although adrenarche typically antedates the onset of gonadal activity (gonadarche) by a few years, the 2 processes do not seem to be causally related, because adrenarche and gonadarche are dissociated in conditions such as central precocious puberty and adrenocortical failure.

The effects of gonadal steroids (testosterone in boys, estradiol in girls) on bone growth and osseous maturation are critical. Both aromatase deficiency and estrogen receptor defects result in delayed epiphyseal fusion and tall stature in affected males. These observations suggest that estrogens, rather than androgens, are responsible for the process of bone maturation that ultimately leads to epiphyseal fusion and cessation of growth. Estrogens also mediate the increased production of growth hormone, which along with a direct effect of sex steroids on bone growth, is responsible for the pubertal growth spurt.

The age of onset of puberty varies and is more closely correlated with osseous maturation than with chronological age (see Chapter 14). In females, the **breast bud** (thelarche) is usually the first sign of **puberty** (10-11 yr of age), followed by the appearance of pubic hair (pubarche) 6-12 mo later. The interval to the onset of **menstrual activity** (menarche) is usually 2-2.5 yr, but may be as long as 6 yr. In the United States, at least 1 sign of puberty is present in approximately 95% of girls by 12 yr of age and in 99% of females by 13 yr of age. Peak height velocity occurs early (at breast stages II-III, typically between 11 and 12 yr of age) in girls and always precedes menarche. The mean age of menarche is approximately 12.75 yr. There are, however, wide variations in the sequence of changes involving growth spurt, breast bud, pubic hair, and maturation of the internal and external genitalia.

In males, **growth of the testes** (≥4 mL in volume or 2.5 cm in longest diameter) and thinning of the scrotum are the first signs of puberty (11-12 yr). These are followed by pigmentation of the scrotum and growth of the penis (see Chapter 14) and by **pubarche.** Appearance of **axillary hair** usually occurs in midpuberty. In males, unlike in females, acceleration of growth begins after puberty is well under way and is maximal at genital stages IV-V (typically between 13 and 14 yr of age). In males, the growth spurt occurs approximately 2 yr later than in females, and growth may continue beyond 18 yr of age.

Genetic and environmental factors affect the timing for the onset of puberty. Population-based studies in the United States and in Europe suggest secular trends for earlier onset of puberty over the past few decades in females and, to a lesser degree, in males. African-American and, to a lesser extent, Hispanic girls appear to be more advanced in the development of secondary sex characteristics for age than white females. The timing of menarche has, however, remained generally stable with only a marginal advancement (2.5-4 mo) reported in U.S.-based studies and no significant change reported in the Copenhagen Puberty Study. The latter also showed that the earlier onset of breast development observed in girls examined in 2006-2008 when compared to those seen in 1991-1993 (means: 10.88 yr vs 9.86 yr, $p < 0.0001$) was not associated with different levels of estradiol or gonadotropins when girls of similar chronological ages were compared between the 2 groups. Hence, earlier breast development may not necessarily reflect an earlier activation of the hypothalamic-pituitary-gonadal axis but could be the consequence of other factors such as increased adiposity or increased exposure to certain environmental agents. Positive correlations between the degree of adiposity and earlier pubertal development in girls have, indeed, been reported. Conversely, female athletes in whom leanness and strenuous physical activity have coexisted from early childhood frequently exhibit a marked delay in puberty or menarche, and they frequently have oligomenorrhea or amenorrhea as adults (see Chapter 691). Pubertal delay is also prevalent in males who are physically very active. These observations support the thesis that the energy balance is closely related to the activity of the GnRH pulse generator and the mechanisms initiating and sustaining puberty via hormonal signals such as leptin or other adipokines.

Chapter 562

Disorders of Pubertal Development

Luigi R. Garibaldi and Wassim Chemaitilly

Precocious puberty is defined by the onset of secondary sexual characteristics before the age of 8 yr in girls and 9 yr in boys. The variation in the age of the onset of puberty in normal children, particularly of different ethnicities, makes this definition somewhat arbitrary. It remains in use by most clinicians.

Depending on the primary source of the hormonal production, precocious puberty may be classified as **central** (also known as **gonadotropin dependent,** or **true**) or **peripheral** (also known as **gonadotropin independent** or **precocious pseudopuberty**) (Table 562-1). **Central** precocious puberty is always isosexual and stems from hypothalamic-pituitary-gonadal activation with ensuing sex hormone secretion and progressive sexual maturation. In **peripheral** precocious puberty, some of the secondary sex characteristics appear, but there is no activation of the normal hypothalamic-pituitary-gonadal interplay. In this latter group, the sex characteristics may be isosexual or heterosexual (contrasexual) (see Chapters 583-588).

Peripheral precocious puberty can induce maturation of the hypothalamic-pituitary-gonadal axis and trigger the onset of central puberty. This mixed type of precocious puberty occurs commonly in conditions such as congenital adrenal hyperplasia, McCune-Albright syndrome, and familial male-limited precocious puberty, when the bone age reaches the pubertal range (10.5-12.5 yr).

Table 562-1 Conditions Causing Precocious Puberty
CENTRAL (GONADOTROPIN-DEPENDENT, TRUE PRECOCIOUS) PUBERTY
Idiopathic
Organic brain lesions
Hypothalamic hamartoma
Brain tumors, hydrocephalus, severe head trauma, myelomeningocele
Hypothyroidism, prolonged and untreated*
COMBINED PERIPHERAL AND CENTRAL
Treated congenital adrenal hyperplasia
McCune-Albright syndrome, late
Familial male precocious puberty, late
PERIPHERAL (GONADOTROPIN-INDEPENDENT, PRECOCIOUS) PSEUDOPUBERTY
GIRLS
Isosexual (feminizing) conditions
McCune-Albright syndrome
Autonomous ovarian cysts
Ovarian tumors
Granulosa–theca cell tumor associated with Ollier disease
Teratoma, chorionepithelioma
SCTAT associated with Peutz-Jeghers syndrome
Feminizing adrenocortical tumor
Exogenous estrogens
Heterosexual (masculinizing) conditions
Congenital adrenal hyperplasia
Adrenal tumors
Ovarian tumors
Glucocorticoid receptor defect
Exogenous androgens
BOYS
Isosexual (masculinizing) conditions
Congenital adrenal hyperplasia
Adrenocortical tumor
Leydig cell tumor
Familial male precocious puberty
Isolated
Associated with pseudohypoparathyroidism
hCG-secreting tumors
• Central nervous system
• Hepatoblastoma
Mediastinal tumor associated with Klinefelter syndrome
Teratoma
Glucocorticoid receptor defect
Exogenous androgen
Heterosexual (feminizing) conditions
Feminizing adrenocortical tumor
SCTAT associated with Peutz-Jeghers syndrome
Exogenous estrogens
INCOMPLETE (PARTIAL) PRECOCIOUS PUBERTY
Premature thelarche
Premature adrenarche
Premature menarche

*Central puberty without true gonadotropin dependency (see text).
hCG, human chorionic gonadotropin; SCTAT, sex-cord tumor with annular tubules.

562.1 Central Precocious Puberty

Luigi R. Garibaldi and Wassim Chemaitilly

Central precocious puberty is defined by the onset of breast development before the age of 8 yr in girls and by the onset of testicular development (volume ≥4 mL) before the age of 9 yr in boys, as a result of the early activation of the hypothalamic-pituitary-gonadal axis. It occurs 5-10–fold more frequently in girls than in boys and is usually sporadic. A high prevalence of idiopathic central precocious puberty has been reported in girls adopted from developing countries, with the limitation that the exact date of birth may be uncertain.

Although approximately 90% of girls have an idiopathic form, a structural central nervous system (CNS) abnormality can be demonstrated in up to 75% of boys with central precocious puberty. Beyond its etiology, which thus needs to be specifically addressed, central precocious puberty can impact linear growth and affect the child's growth potential.

CLINICAL MANIFESTATIONS

Sexual development may begin at any age and generally follows the sequence observed in normal puberty. In girls, early menstrual cycles may be more irregular than they are with normal puberty. The initial cycles are usually anovulatory, but pregnancy has been reported as early as 5.5 yr of age (Fig. 562-1). In boys, testicular biopsies have shown stimulation of all elements of the testes, and spermatogenesis has been observed as early as 5-6 yr of age. In affected girls and boys, height, weight, and osseous maturation are advanced. The increased rate of bone maturation results in early closure of the epiphyses, and the ultimate stature is less than it would have been otherwise. Without treatment, approximately 30% of girls and an even larger percentage of boys achieve a height less than the 5th percentile as adults. Mental development is usually compatible with chronological age. Emotional behavior and mood swings are common, but serious psychologic problems are rare.

Although the clinical course is variable, 3 main patterns of pubertal progression can be identified. Most girls (particularly those younger than 6 yr of age at the onset) and a large majority of boys have rapidly progressive puberty, characterized by rapid physical and osseous maturation, leading to a loss of height potential. An increasing percentage of girls (older than 6 yr of age at the onset with an idiopathic form) have a slowly progressive variant, characterized by parallel advancement of osseous maturation and linear growth, with preserved height potential. Spontaneously regressive or unsustained central precocious

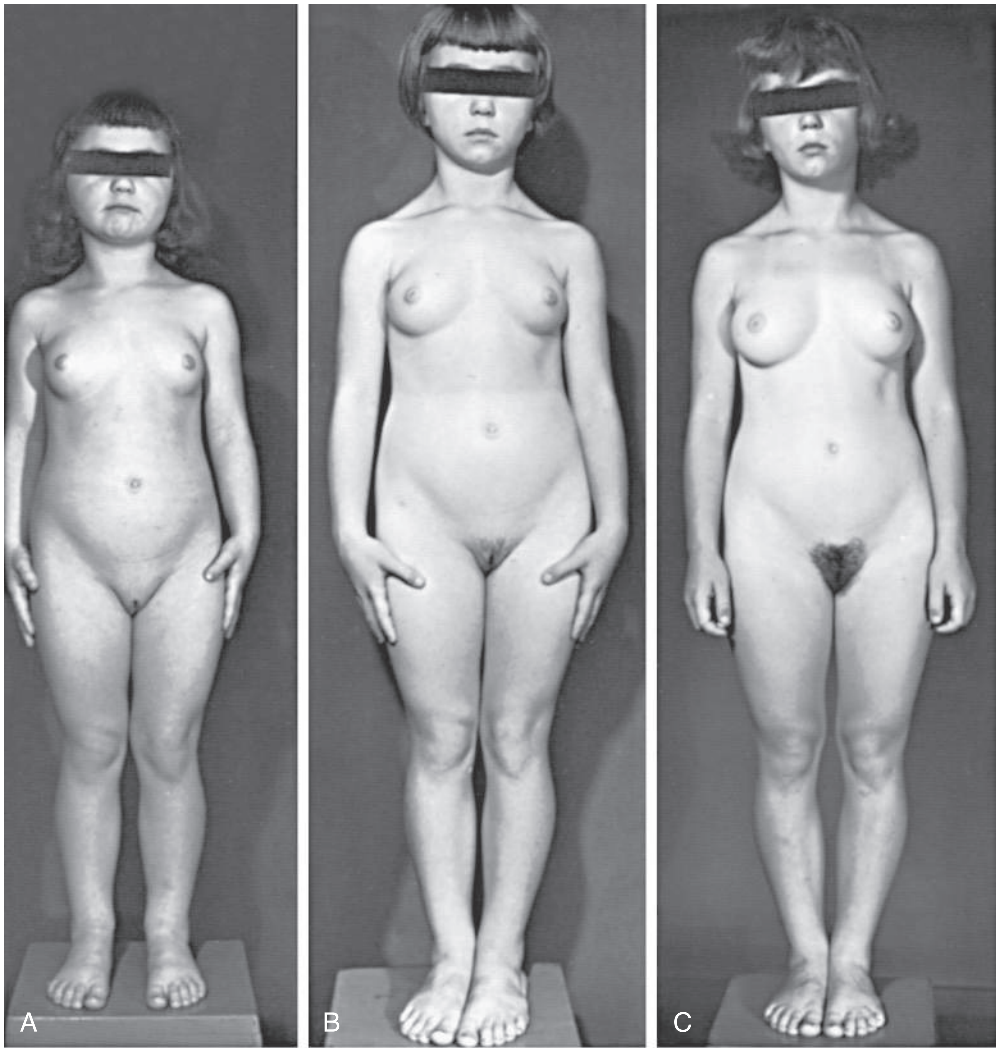

Figure 562-1 Natural course of idiopathic central precocious puberty. Patient **(A)** at $3\frac{11}{12}$, **(B)** at $5\frac{2}{3}$, and **(C)** at 8.5 yr of age. Breast development and vaginal bleeding began at 2.5 yr of age. Bone age was 7.5 yr at $3\frac{11}{12}$ yr of age, and 14 yr at 8 yr of age. Intelligence and dental age were normal for chronological age. Growth was completed at 10 yr; ultimate height was 142 cm (56 in). No effective therapy was available at the time this patient sought medical attention.

puberty is quite rare. This variability in the natural course of sexual precocity underscores the need for longitudinal observation at the onset of sexual development, before treatment is considered.

LABORATORY FINDINGS

Sex hormone concentrations are usually appropriate for the stage of puberty in both sexes. Despite the availability of sensitive and specific (liquid chromatography/tandem mass spectrometry) assays for sex hormones, serum estradiol concentrations are low or undetectable in the early phase of sexual precocity in girls, as they are in normal puberty. In boys, serum testosterone levels are usually detectable or clearly elevated by the time the parents seek medical attention, provided that an early morning blood sample is obtained. With the use of highly sensitive immunofluorometric and chemiluminescent assays, serum luteinizing hormone (LH) concentrations are undetectable in prepubertal children in random blood samples, but become detectable in 50-75% of girls and a higher percentage of boys with central sexual precocity. Unfortunately, a number of hospitals use only moderately sensitive immunoenzymatic assays for LH, and often insensitive assays for estradiol and testosterone, which decrease the diagnostic sensitivity of these measurements. Measurement of LH in serial blood samples obtained during sleep has greater diagnostic power than measurement in a single random sample, and it typically reveals a well-defined pulsatile secretion of LH. Intravenous administration of gonadotropin-releasing hormone (GnRH stimulation test) or a GnRH agonist (leuprolide stimulation test) is a helpful diagnostic tool, particularly for boys, in whom a "pubertal" LH response (LH peak >5 IU/L) with predominance of LH over follicle-stimulating hormone (FSH) tends to occur early in the course of precocious puberty. In girls with sexual precocity, however, the nocturnal LH secretion and the LH response to GnRH or GnRH agonist may be quite low at breast stages II to early III (immunometric LH peak, <5 IU/L), and the LH:FSH ratio may remain low until mid-advanced puberty. In such girls with "low" LH response, the central nature of sexual precocity can be proven by detecting pubertal levels of estradiol (>50 pg/mL), 20-24 hr after stimulation with leuprolide.

Osseous maturation is variably advanced, often by more than 2-3 SD. Pelvic ultrasonography in girls reveals progressive enlargement of the ovaries, followed by enlargement of the fundus and then of the whole uterus to pubertal size. An MRI scan usually demonstrates physiologic enlargement of the pituitary gland, as seen in normal puberty; it may also reveal CNS pathology (see Chapter 562.2).

DIFFERENTIAL DIAGNOSIS

Organic CNS causes of central sexual precocity are more likely in boys, and those girls who have rapid breast development, have estradiol

>30 pg/mL, or are younger than 6 yr of age. All children in these categories should undergo MRI scans of the brain and pituitary gland. Specific criteria for ordering brain imaging in girls older than age 6 yr are still lacking, although some authorities recommend MRI scans for all children with central precocious puberty.

Gonadotropin-independent causes of isosexual precocious puberty must be considered in the differential diagnosis (see Table 562-1). For girls, these include tumors of the ovaries, autonomously functioning ovarian cysts, feminizing adrenal tumors, McCune-Albright syndrome, and exogenous sources of estrogens. In boys, congenital adrenal hyperplasia, adrenal tumors, Leydig cell tumors, chorionic gonadotropin–producing tumors, exposure to exogenous androgens, and familial male precocious puberty should be considered.

TREATMENT

Virtually all boys and the large subgroup of girls with rapidly progressive precocious puberty are candidates for treatment. Girls with slowly progressive idiopathic central precocious puberty do not seem to benefit in terms of height prognosis from GnRH-agonist therapy. Former small-for-gestational-age infants may be at greater risk of short stature as adults and may require more aggressive treatment of precocious puberty, possibly in conjunction with human growth hormone therapy. Certain patients require treatment solely for psychologic or social reasons, including children with special needs and very young girls at risk of early menarche.

The observation that the pituitary gonadotropic cells require pulsatile, rather than continuous, stimulation by GnRH to maintain the ongoing release of gonadotropins provides the rationale for using GnRH agonists for treatment of central precocious puberty. By virtue of being more potent, and having a longer duration of action, than native GnRH, these GnRH agonists (after a brief period of stimulation) "desensitize" the gonadotropic cells of the pituitary to the stimulatory effect of endogenous GnRH and effectively halt the progression of central sexual precocity.

Long-acting formulations of GnRH agonists, which maintain fairly constant serum concentrations of the drug for weeks or months, constitute the preparations of choice for treatment of central precocious puberty. In the United States, the available preparations include: (1) leuprolide acetate (Lupron Depot-Ped), in a dose of 0.25-0.3 mg/kg (minimum 7.5 mg) intramuscularly once every 4 wk; (2) longer-acting preparations of depot leuprolide, allowing for injections (11.25-30.0 mg intramuscularly) every 90 days; and (3) histrelin (Supprelin LA), a subcutaneous 50 mg implant with effects lasting 12 mo. Other preparations (D-Trp6-GnRH [Decapeptyl], goserelin acetate [Zoladex]) are approved for treatment of precocious puberty in other countries. Recurrent sterile fluid collections at the sites of injections are an uncommon local side effect and occur in less than 1-3% of patients treated with depot leuprolide. Breakage or malfunction of the histrelin implant is very rare. Other available treatment options, usually reserved for children who cannot tolerate the products listed above, include subcutaneous injections of aqueous leuprolide, given once or twice daily (total dose 60 μg/kg/24 hr), or intranasal administration of the GnRH agonist nafarelin (Synarel), 800 μg bid. The potential for irregular compliance with daily administration, as well as the variable absorption of the intranasal route for nafarelin, may limit the long-term benefit of the latter preparations on adult height. GnRH antagonists have not been investigated sufficiently and are not FDA approved. Oral GnRH antagonists are also being investigated.

Treatment results in decrease of the growth rate, generally to age-appropriate values, and an even greater decrease of the rate of osseous maturation. Some children, particularly those with greatly advanced (pubertal) bone age, may show marked deceleration of their growth rate and a complete arrest in the rate of osseous maturation. Treatment results in enhancement of the predicted height, although the actual adult height of patients followed to epiphyseal closure is approximately 1 SD less than their midparental height. In girls, breast development may regress in those with Tanner stages II-III development. Most commonly, the size of the breasts remains unchanged in girls with stages III-V development, or may even increase slightly because of progressive adipose tissue deposition. The amount of glandular tissue decreases. Pubic hair usually remains stable in girls, or may progress slowly during treatment, reflecting the gradual increase in adrenal androgens. Menses, if present, cease. Pelvic sonography demonstrates a decrease of the ovarian and uterine size. In boys, there is decrease of testicular size, variable regression of pubic hair, and decrease in the frequency of erections. Except for a reversible decrease in bone density (of uncertain clinical significance), no serious adverse effects of GnRH analogs have been reported in children treated for sexual precocity. If treatment is effective, the serum sex hormone concentrations decrease to prepubertal levels (testosterone, <10-20 ng/dL in boys; estradiol, <5-10 pg/mL in girls). The serum LH and FSH concentrations, as measured by sensitive immunometric assays, decrease to less than 1 IU/L in most patients, although almost never does the LH return to truly prepubertal levels (<0.1 IU/L). Moreover, the incremental FSH and LH responses to GnRH stimulation decrease to less than 2-3 IU/L. Serum LH and sex hormone levels remain suppressed for as long as therapy is continued, but puberty resumes promptly when therapy is discontinued, typically at a "pubertal" chronological age. In girls, menarche generally appears at an average of 18 mo (range: 6-24 mo) of cessation of intramuscular therapy, and somewhat earlier after removal of the histrelin implant. The addition of human growth hormone to GnRH agonists has been used on an investigational basis in children with precocious puberty, markedly advanced bone age, and prediction of short stature. The available, albeit limited, data indicate that combined therapy may increase the adult height.

562.2 Precocious Puberty Resulting from Organic Brain Lesions

Wassim Chemaitilly and Luigi R. Garibaldi

ETIOLOGY

Hypothalamic hamartomas are the most common brain lesion causing central precocious puberty (Fig. 562-2). This congenital malformation consists of ectopically located neural tissue. Glial cells within the hamartoma have been shown to produce transforming growth factor α, which has the potential to activate the GnRH pulse generator. On MRI, it appears as a small pedunculated mass attached to the tuber cinereum or the floor of the third ventricle or, less often, as a sessile mass (Fig. 562-3) that remains static in size over years. Hypothalamic hamartomas, especially the sessile variant, can be associated with gelastic or psychomotor seizures.

A wide variety of other CNS lesions or insults, usually involving the hypothalamus by scarring, invasion, or pressure, are associated with gonadotropin-dependent sexual precocity. They include postencephalitic scars, tuberculous meningitis, tuberous sclerosis, severe head trauma, and hydrocephalus, either isolated or associated with myelomeningocele. Neoplasms causing precocious puberty include astrocytomas, ependymomas, and optic tract tumors. Tumors of the latter type (typically slowly progressive or indolent optic gliomas) are highly prevalent (15-20%) in children with neurofibromatosis type 1 and constitute the main etiologic factor for the central sexual precocity encountered in a small subset (approximately 3%) of children with neurofibromatosis type 1.

Approximately 50% of the tumors in the pineal region are germ cell tumors or astrocytomas; the remainder consist of a wide variety of histologically distinct tumor types. In boys, pineal or hypothalamic germ cell tumors can cause central precocious puberty by secreting human chorionic gonadotropin (hCG), which stimulates the LH receptors in the Leydig cells of the testes (see Chapter 562.5).

CLINICAL MANIFESTATIONS

Some of these tumors or malformations (hypothalamic hamartomas) remain static in size or grow slowly, producing no signs other than precocious puberty. For lesions causing neurologic symptoms, the neuroendocrine manifestations may be present for 1-2 yr before the tumor can be detected radiologically. Hypothalamic signs or symptoms such

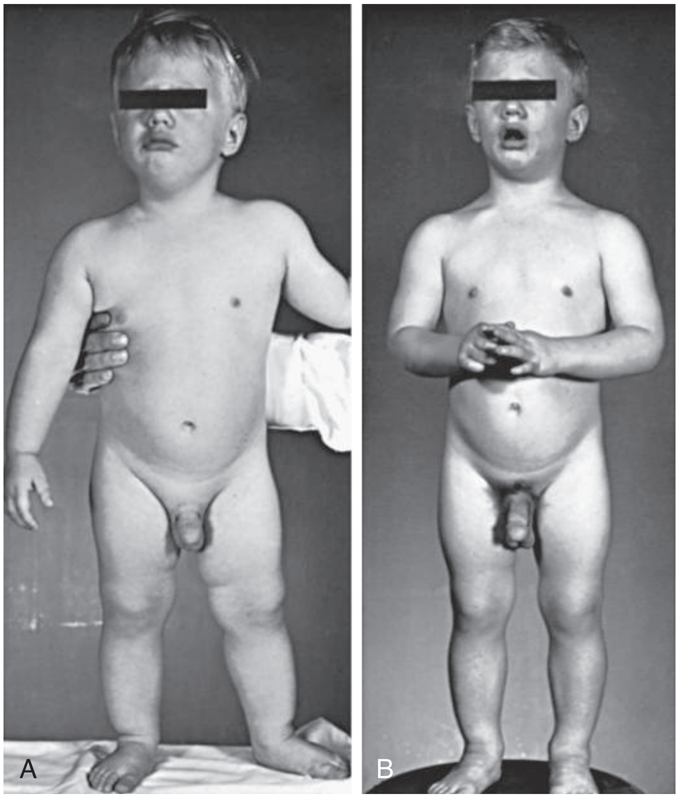

Figure 562-2 **Natural course of precocious puberty with central nervous system lesion.** Photographs at 1.5 **(A)** and 2.5 **(B)** yr of age. Accelerated growth, muscular development, osseous maturation, and testicular development were consistent with the degree of secondary sexual maturation. In early infancy, the patient began having frequent spells of rapid, purposeless motion; later in life, he had episodes of uncontrollable laughing with ocular movements. At 7 yr, he exhibited emotional lability, aggressive behavior, and destructive tendencies. Although a hypothalamic hamartoma had been suspected, it was not established until CT scanning became available when the patient was 23 yr of age. Epiphyses fused at 9 yr of age; final height was 142 cm (56 in). At 24 yr of age, he developed an embryonal cell carcinoma of the retroperitoneum.

as diabetes insipidus, adipsia, hyperthermia, unnatural crying or laughing (gelastic seizures), obesity, and cachexia should suggest the possibility of an intracranial lesion. Visual signs (proptosis, decreased visual acuity, visual field defects) may be the first manifestation of an optic glioma.

The sexual precocity is always isosexual, and the endocrine patterns are generally those found in children without demonstrable organic lesions. Rapidly progressive sexual precocity in very young children suggests the likelihood of a hypothalamic hamartoma. In conditions other than hypothalamic hamartoma, growth hormone deficiency can occur and may be masked by the growth-promoting effect of the increased sex hormone levels.

TREATMENT

Regardless of the cause, therapy with GnRH agonists is as effective in children with organic brain lesions causing central precocious puberty, and these analogs are the therapy of choice to halt premature sexual development. This includes patients with a hypothalamic hamartoma, if precocious puberty is its only manifestation. In patients with hypothalamic hamartoma and associated intractable gelastic or psychomotor seizures, however, stereotactic radiation therapy (gamma knife surgery) is effective and less risky than neurosurgical intervention. For other neurologic lesions, therapy depends on the nature and location of the pathologic process. Combined growth hormone therapy

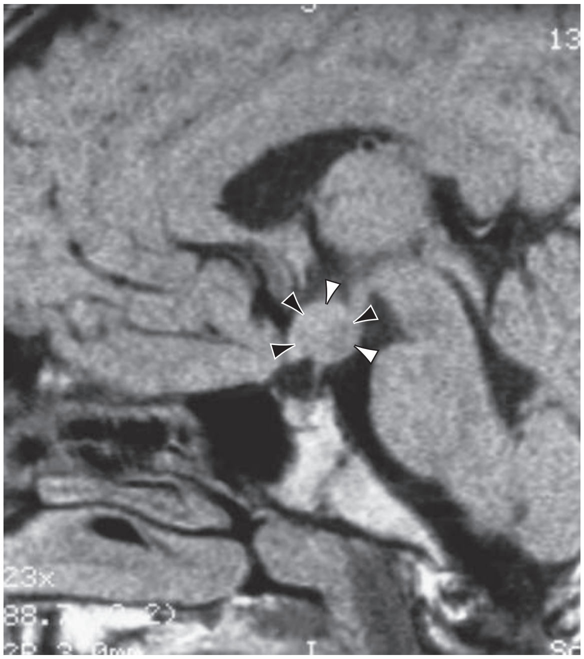

Figure 562-3 **MRI of a central nervous system lesion in a child with central precocious puberty.** A 6 yr old girl was referred for stage IV breast development and growth acceleration. Serum luteinizing hormone and estradiol concentrations were in the adult range. The midsagittal T1-weighted image shows an isointense hypothalamic mass *(arrowheads)*, typical of a hamartoma. *(From Sharafuddin M, Luisiri A, Garibaldi LR, et al: MR imaging diagnosis of central precocious puberty: importance of changes in the shape and size of the pituitary gland,* AJR Am J Roentgenol *162:1167–1173, 1994.)*

should be considered for patients with associated growth hormone deficiency.

562.3 Precocious Puberty Following Irradiation of the Brain

Wassim Chemaitilly and Luigi R. Garibaldi

Radiation therapy, generally for leukemia or intracranial tumors, increases the risk of precocious puberty considerably, whether the irradiation is directed to the hypothalamic area or to areas of the brain anatomically distant from the hypothalamus. Low-dose radiation (18-24 Gy) hastens the onset of puberty almost exclusively in girls. High-dose radiation (25-47 Gy), conversely, appears to trigger precocious sexual development in both sexes, and the risk of sexual precocity is inversely proportional to the age of the child at the time radiation was given.

This type of sexual precocity is often associated with growth hormone deficiency and may also be combined with other conditions (spinal irradiation, hypothyroidism) adversely affecting the prognosis for a reasonable adult height. Unless careful attention is paid to early signs of pubertal development in these children, the combination of growth hormone deficiency and the growth-promoting effect of sex steroids often results in a "normal" growth rate at the expense of a rapidly advancing bone age and impaired adult height potential.

TREATMENT

GnRH analogs are effective in arresting pubertal progression in this patient population. However, concomitant growth hormone deficiency (and/or thyroid hormone deficiency) should be diagnosed and treated promptly in order for the adult height prognosis to improve.

Paradoxically, hypopituitarism with gonadotropin deficiency may subsequently develop as a late effect of high-dose CNS irradiation in patients with or without a history of precocious puberty, and it may require substitution therapy with sex steroids.

562.4 Syndrome of Precocious Puberty and Hypothyroidism

Luigi R. Garibaldi and Wassim Chemaitilly

In children with untreated hypothyroidism, the onset of puberty is usually delayed until epiphyseal maturation reaches 12-13 yr of age. Precocious puberty in a child with untreated hypothyroidism and a prepubertal bone age presents a strikingly unphysiologic association, yet is common and may occur in as many as 50% of children with severe hypothyroidism of long duration. These children have the usual manifestations of hypothyroidism, including retardation of growth and of osseous maturation (see Chapter 565). The cause of the hypothyroidism is usually Hashimoto thyroiditis, which often goes undiagnosed, especially in children with special needs such as those with trisomy 21, in whom the symptoms of profound hypothyroidism may be more difficult to recognize. Sexual development in girls consists of breast enlargement and menstrual bleeding; the latter may occur even in girls with minimal breast enlargement. Pelvic sonography may reveal large, multicystic ovaries. Boys have testicular enlargement associated with modest or no penile enlargement. No pubic hair development occurs in either girls or boys. Enlargement of the sella, which is typical of long-standing primary hypothyroidism, may be demonstrated by skull film or MRI. Plasma levels of thyroid-stimulating hormone (TSH) are markedly elevated, often greater than 500 μU/mL, and those of prolactin and estradiol are mildly elevated. Although serum FSH is low and LH is undetectable, when measured by specific assays, the massively elevated concentrations of TSH appear to interact with the FSH receptor ("specificity spillover"), thus inducing FSH-like effects in the absence of LH effects on the gonads. The FSH-like effect suffices to induce estradiol secretion by the ovaries, while in boys testicular enlargement occurs without substantial testosterone secretion. Thus, the precocious puberty associated with hypothyroidism behaves as an incomplete form of gonadotropin-dependent puberty. Treatment of the hypothyroidism results in rapid return to normal of the biochemical and clinical manifestations. Possible progression to central puberty with rapid bone age advancement could occur in the months following the initiation of thyroid hormone replacement, a complication that would justify delaying puberty with GnRH analogs. Macroorchidism (testicular volume >30 mL) may persist in adult males despite adequate levothyroxine therapy.

562.5 Chorionic Gonadotropin-Secreting Tumors

Luigi R. Garibaldi and Wassim Chemaitilly

These are rare tumors, whose secretion of hCG stimulates the LH receptors in the Leydig cells. The testicles are only minimally enlarged, and the histology reveals interstitial cell hyperplasia with no spermatogenesis. Plasma levels of testosterone are elevated, while those of FSH and LH, as measured by specific immunometric assays, are low. These tumors induce puberty in boys but not in girls, as ovarian production of estrogens cannot take place in the absence of FSH stimulation.

HEPATIC TUMORS

All reported cases of **hepatoblastoma** causing isosexual precocious puberty have been in boys, with the average age of onset of 2 yr (range: 4 mo to 8 yr). An enlarged liver or mass in the right upper quadrant should suggest the diagnosis. Plasma levels of hCG and α-fetoprotein are usually markedly elevated and serve as useful markers for following the effects of therapy. Similarly to other carcinomas of the liver; the prognosis for survival beyond 1-2 yr from the time of diagnosis is poor.

INTRACRANIAL TUMORS

Nongerminomatous or mixed germ cell tumors, choriocarcinomas, teratomas, teratocarcinomas, and others account for <5% of intracranial tumors. They are usually located in the neurohypophyseal area or the pineal area and may cause precocious puberty in boys if they secrete hCG, and rarely in girls because of mass effect. Marked elevations of hCG and α-fetoprotein often occur in the cerebrospinal fluid, although elevations in the blood may be modest. Treatment includes radiation, chemotherapy, and debulking surgery.

TUMORS IN OTHER LOCATIONS

Very rare locations include the mediastinum, gonads, or even adrenal glands. Mediastinal tumors have been reported to cause precocious puberty in boys with Klinefelter syndrome.

PERIPHERAL PRECOCIOUS PUBERTY

The adrenal causes of pseudopuberty are discussed in Chapter 576, and the gonadal causes are discussed in Chapters 584 and 587.

562.6 McCune-Albright Syndrome (Precocious Puberty with Polyostotic Fibrous Dysplasia and Abnormal Pigmentation)

Wassim Chemaitilly and Luigi R. Garibaldi

This syndrome of endocrine dysfunction is associated with patchy cutaneous pigmentation and fibrous dysplasia of the skeletal system. It is a rare condition with a prevalence between 1 in 100,000 and 1 in 1,000,000 people. A classical cause of peripheral precocious puberty, it can also induce pituitary, thyroid, and adrenal aberrations. It is characterized by autonomous hyperfunction of many glands and is caused by a missense mutation in the gene encoding the α-subunit of G_S, the G protein that stimulates cyclic adenosine monophosphate formation, resulting in the formation of the putative gsp oncoprotein. Activation of receptors (corticotropin [adrenocorticotropic hormone (ACTH)], TSH, FSH, and LH receptors) that operate via a cyclic adenosine monophosphate–dependent mechanism, as well as cell proliferation, ensue. Because the mutation is somatic rather than genomic, it is expressed differently in different tissues; hence the variability of clinical expression. Precocious puberty has been described predominantly in girls (Fig. 562-4). The average age at onset in affected girls is about 3 yr, but vaginal bleeding has occurred as early as 4 mo of age and secondary sex characteristics have occurred as early as 6 mo. Young girls have suppressed levels of LH and FSH, and there is no response to GnRH or leuprolide stimulation. Estradiol levels vary from normal to markedly elevated (>900 pg/mL), are often cyclic, and may correlate with the size of the recurrent ovarian cysts. In boys, precocious puberty is less common but has been reported in several instances. Unlike ovarian enlargement in girls, testicular enlargement in boys is fairly symmetric. It is followed by the appearance of phallic enlargement and pubic hair, as in normal puberty. Testicular histology has demonstrated large seminiferous tubules and no or minimal Leydig cell hyperplasia; these findings may simply reflect the fact that biopsy specimens were obtained at an early stage of pubertal development. In girls and boys, when the bone age reaches the usual pubertal age range, gonadotropin secretion begins, and the response to GnRH becomes pubertal. Central precocious puberty overrides the antecedent (gonadotropin-independent) precocious pseudopuberty. In girls, menses become more regular, but often not completely so, and fertility has been documented.

Pubertal progression is variable in these patients. Functioning ovarian cysts often disappear spontaneously; aspiration or surgical excision of cysts is rarely indicated, but ovarian torsion may occur.

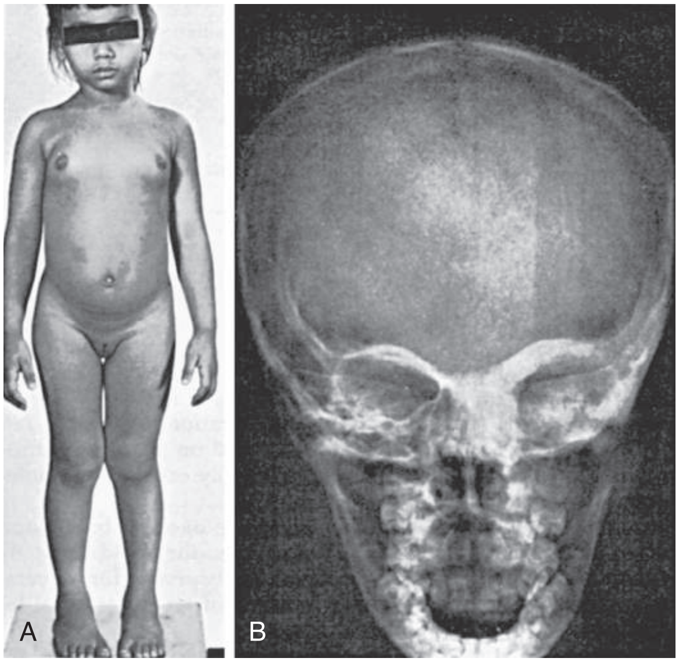

Figure 562-4 Precocious puberty associated with polyostotic fibrous dysplasia (McCune-Albright syndrome) in a girl 4.5 yr of age; at this time, her height age and bone age were normal. Menarche occurred at 4 yr of age. **A,** Note the bilateral breast development, hyperpigmented spots on the abdomen, and prominence of the left side of the face. **B,** Roentgenograms revealed fibrous dysplasia in the distal end of the left ulna and thickening of the bones about the left orbit and the maxillary portion of the frontal bones shown here.

For girls with persistent estradiol secretion, agents that interfere with the final step of estrogen biosynthesis (i.e., aromatase inhibitors such as letrozole [1.25-2.5 mg/day orally]) or antiestrogens (such as tamoxifen 5-20 mg/day orally) may limit, to a variable extent, the estrogen effects on pubertal and osseous maturation. The same compounds have also been used in boys, in combination with antiandrogens (such as spironolactone 50-100 mg bid, flutamide 125-250 mg bid, or bicalutamide 25-50 mg daily). These compounds are not approved by the FDA for this indication; tamoxifen, flutamide, and bicalutamide may be hepatotoxic, and high-dose spironolactone may (rarely) cause hyperkalemia. Associated therapy with long-acting analogs of GnRH is indicated only for patients whose puberty has shifted from a gonadotropin-independent to a predominantly gonadotropin-dependent mechanism.

EXTRAGONADAL MANIFESTATIONS

The hyperthyroidism that occurs in this condition differs from that characteristic of Graves disease. There is an equal distribution between male and female patients; the goiters are multinodular. Clinical hyperthyroidism is uncommon in children, but goiters, mildly elevated triiodothyronine levels, suppressed TSH levels, and abnormalities on ultrasound have been reported. Thyroidectomy is rarely necessary.

In patients with associated Cushing syndrome, bilateral nodular adrenocortical hyperplasia has occurred in early infancy, antedating the sexual precocity. ACTH levels are low, and adrenal function is not suppressed by large doses of dexamethasone. Treatment is bilateral adrenalectomy.

Increased secretion of growth hormone occurs uncommonly and is manifested clinically by gigantism or acromegaly or by increased rates of growth even in the absence of precocious puberty. Girls and boys are equally affected. Serum levels of growth hormone are elevated, increase during sleep, and are poorly inhibited by oral glucose. Serum levels of prolactin are increased in most patients, but fewer than 50% of the patients have a demonstrable pituitary tumor. Depot octreotide (Sandostatin LAR Depot 10-30 mg IM monthly) or Lanreotide (Somatuline Depot, 60-90 mg SC monthly), long-acting somatostatin analogs, can be used to treat the hypersomatotropism. The prognosis is favorable for longevity, but deformities, repeated fractures, pain, and occasional cranial nerve compression may result from the bony lesions.

Of the extraglandular manifestations, phosphaturia, leading to rickets or osteomalacia, is the most common. Cardiovascular and hepatic involvement is rare but may be life-threatening (severe neonatal cholestasis).

562.7 Familial Male Gonadotropin-Independent Precocious Puberty

Wassim Chemaitilly and Luigi R. Garibaldi

This rare, autosomal dominant form of peripheral precocious puberty is transmitted from affected males and unaffected female carriers of the gene to their male offspring. Signs of puberty appear by 2-3 yr of age. The testes are only slightly enlarged. Testicular biopsies show Leydig cell maturation and, sometimes, marked hyperplasia. Maturation of seminiferous tubules may be present. Testosterone levels are variably and often markedly elevated, even above the adult male range; however, baseline levels of LH are prepubertal, pulsatile secretion of LH is absent, and LH does not respond to stimulation with GnRH or GnRH agonist. The cause for activation of Leydig cells independently of gonadotropin stimulation is a missense mutation of the LH receptor leading to constitutive activation of cyclic adenosine monophosphate production. Osseous maturation may be markedly advanced; when it reaches the pubertal age range, hypothalamic maturation shifts the mechanism of pubertal development to a gonadotropin-dependent one. This sequence of events is similar to that occurring in children with McCune-Albright syndrome (see Chapter 562.6) or in those with congenital adrenal hyperplasia (see Chapter 576.1).

Gonadotropin-independent precocious puberty has been diagnosed in a few unrelated boys with type IA pseudohypoparathyroidism who had a single mutation of the $G_s\alpha$ protein. This mutation is inactivating at normal body temperature and causes pseudohypoparathyroidism, but in the cooler temperature of the testes, it is constitutionally activating, resulting in adenyl cyclase stimulation and production of testosterone. Although this mutation differs from the constitutive LH receptor mutation, which usually causes familial male gonadotropin-independent precocious puberty, the end result is the same.

TREATMENT

Young boys have been successfully treated with ketoconazole (600 mg/24 hr in 8 hr divided doses), an antifungal drug that inhibits C-17,20-lyase and testosterone synthesis. Other investigators use a combination of antiandrogens (such as spironolactone 50-100 mg twice a day, flutamide 125–250 mg twice a day, or bicalutamide 25-50 mg daily) and aromatase inhibitors (letrozole 2.5 mg/day, or anastrozole 1 mg/day), because estrogens derived from androgens stimulate bone maturation. These medications are unable to revert the serum testosterone to the normal (prepubertal) concentrations or completely offset the unfavorable effects of the elevated sex hormones. They slow down, but do not halt, the progression of puberty and may not improve the height prognosis. Boys whose GnRH pulse generator has matured require combined therapy with GnRH agonists.

562.8 Incomplete (Partial) Precocious Development

Luigi R. Garibaldi and Wassim Chemaitilly

Isolated manifestations of precocity without development of other signs of puberty are not unusual; development of the breasts in girls and growth of sexual hair in both sexes are the 2 most common forms.

PREMATURE THELARCHE

This term applies to a sporadic, transient condition of isolated breast development that most often appears in the 1st 2 yr of life. In some girls, breast development is present at birth and persists. It may be unilateral or asymmetric and often fluctuates in degree. Growth and osseous maturation are normal or slightly advanced. The genitalia show no evidence of estrogenic stimulation. Breast development may regress after 2 yr, often persists for 3-5 yr, and is rarely progressive. Menarche occurs at the expected age, and reproduction is normal. Basal serum levels of FSH and the FSH response to GnRH stimulation may be greater than that seen in normal controls. Plasma levels of LH and estradiol are consistently less than the limits of detection. Ultrasound examination of the ovaries reveals normal size, but a few small (<9 mm) cysts are not uncommon.

In some girls, breast development may be associated with definite evidence of systemic estrogen effects, such as growth acceleration or bone age advancement. Pelvic sonography may reveal enlarged ovaries or uterus. This condition, referred to as **exaggerated or atypical thelarche,** differs from central precocious puberty because it spontaneously regresses. Leuprolide or GnRH stimulation elicits a robust FSH response, a low LH response, and (after leuprolide only) a moderate estradiol increment at 24 hr (average: 60-90 pg/mL). The pathogenesis of typical and exaggerated forms of thelarche is unclear. Delayed inactivation of the hypothalamic-pituitary-ovarian axis, which is active during the prenatal and early postnatal period, increased peripheral sensitivity to estrogens, and other possibilities have been proposed, yet are unproven hypotheses. Premature thelarche is a benign condition but may be the first sign of true or peripheral precocious puberty, or it may be caused by exogenous exposure to estrogens. In addition to a detailed history, a bone age should be obtained if there are any unusual features. Random serum concentrations of FSH, LH, and estradiol are generally low and not diagnostic. Pelvic ultrasound examination or leuprolide stimulation testing is rarely indicated. Continued observation is important because the condition cannot be readily distinguished from true precocious puberty. Regression and recurrence suggest functioning follicular cysts. Occurrence of thelarche in children older than 3 yr of age most often is caused by a condition other than benign premature thelarche.

PREMATURE PUBARCHE (ADRENARCHE)

Premature adrenarche has traditionally applied to the appearance of sexual hair before the age of 8 yr in girls or 9 yr in boys without other evidence of maturation. It is much more frequent in girls than in boys. The higher prevalence of this condition in African-American and, to a smaller extent, Latino girls in comparison to white girls may suggest that the cutoff age for the definition of "premature" should be adjusted for different ethnic groups on the basis of epidemiologic data. Hair appears on the mons and labia majora in girls and perineal and scrotal area in boys; axillary hair generally appears later. Adult-type axillary odor is common. Affected children are often slightly advanced in height and osseous maturation. Premature adrenarche is an early maturational event of adrenal androgen production. This event coincides with precocious maturation of the zona reticularis, an associated decrease in 3β-hydroxysteroid dehydrogenase activity, and an increase in C-17,20-lyase activity. These enzymatic changes result in increased basal and ACTH-stimulated serum concentrations of the Δ^5-steroids (17-hydroxypregnenolone and dehydroepiandrosterone) and, to a lesser extent, of the Δ^4-steroids (particularly androstenedione) compared with age-matched control subjects. The levels of these steroids and of dehydroepiandrosterone sulfate are usually comparable to those of older children in the early stages of normal puberty. Idiopathic premature adrenarche is a slowly progressive condition that requires no therapy. However, a subset of patients with precocious pubarche has 1 or more features of systemic androgen effect, such as marked growth acceleration, clitoral (girls) or phallic (boys) enlargement, cystic acne, or advanced bone age (>2 SD above the mean for age). In these patients with **atypical premature adrenarche,** an ACTH stimulation test with measurement of steroid intermediates (mainly, serum 17-hydroxyprogesterone concentrations) is indicated to rule out nonclassical congenital adrenal hyperplasia caused by 21-hydroxylase deficiency. Epidemiologic and molecular genetic studies show that the prevalence of nonclassical 21-hydroxylase deficiency is approximately 3-6% of unselected children with precocious pubarche; the prevalence of other enzyme defects (i.e., 3β-hydroxysteroid dehydrogenase or 11β-hydroxylase deficiency) is extremely low. Although idiopathic premature adrenarche has been considered a benign condition, longitudinal observations suggest that approximately 50% of girls with premature adrenarche are at high risk for **hyperandrogenism** and **polycystic ovary syndrome,** alone or more often in combination with other components of the so-called metabolic syndrome (insulin resistance possibly progressing to type 2 diabetes mellitus, dyslipidemia, hypertension, increased abdominal fat) as adults. Whether the unfavorable progression to pubertal hyperandrogenism can be prevented by insulin-sensitizing agents (metformin 850-1,000 mg/day) or lifestyle interventions (diet, exercise) remains to be proven in large studies. An increased risk of premature adrenarche and the metabolic syndrome is documented in children born small for their gestational age. This appears to be associated with insulin resistance and decreased β-cell reserve, perhaps as a consequence of fetal undernutrition.

PREMATURE MENARCHE

This is a rare entity, much less frequent than premature thelarche or premature adrenarche, and is a diagnosis of exclusion. In girls with isolated vaginal bleeding in the absence of other secondary sexual characteristics, more common causes, such as vulvovaginitis, a foreign body (typically associated with malodorous discharge), or sexual abuse, and uncommon causes, such as urethral prolapse and sarcoma botryoides, must be carefully excluded. The majority of girls with idiopathic premature menarche have only 1-3 episodes of bleeding; puberty occurs at the usual time, and menstrual cycles are normal. Plasma levels of gonadotropins are low, but estradiol levels may be occasionally elevated, probably owing to episodic ovarian estrogen secretion associated with ovarian follicular cysts that can be detected on ultrasound.

562.9 Medicational Precocity

Luigi R. Garibaldi and Wassim Chemaitilly

A variety of medicaments can induce the appearance of secondary sexual characteristics that may be confused with precocious puberty. A careful history focused on exploring the possibility of accidental exposure to, or ingestion of, sex hormones is important. Peripheral precocious puberty has occurred in boys and girls from the accidental ingestion of estrogens (including contraceptive pills) and from the administration of anabolic steroids. The most common cause of medicational precocity is currently related to the widespread use of testosterone gels or creams that are applied to the skin for treatment of male hypogonadism. This has resulted in virilization of children and women following skin contact at, and systemic absorption from, the area where the gel/cream was applied by their family member.

Less commonly, estrogens in cosmetics, hair creams, and breast augmentation creams have caused breast development in girls and gynecomastia in boys, via percutaneous absorption. The high prevalence of premature thelarche and peripheral precocious puberty in Puerto Rico has been attributed to contamination of meats, particularly chicken, with estrogens used in animal husbandry, but has not been proved. Exogenous estrogens may produce a darkening of the areola that is not usually seen in endogenous types of precocity. The precocious changes disappear after cessation of exposure to the hormones.

Section 2

Disorders of the Thyroid Gland

Chapter 563

Thyroid Development and Physiology

Stephen H. LaFranchi and Stephen A. Huang

FETAL DEVELOPMENT

The fetal thyroid arises from an outpouching of the foregut at the base of the tongue (foramen cecum). It migrates to its normal location over the thyroid cartilage by 8-10 wk of gestation. The thyroid bilobed shape is recognized by 7 wk of gestation, and characteristic thyroid follicle cell and colloid formation is seen by 10 wk. Thyroglobulin synthesis occurs from 4 wk, iodine trapping occurs by 8-10 wk, and thyroxine (T_4) and, to a lesser extent, triiodothyronine (T_3) synthesis and secretion occur from 12 wk of gestation. There is evidence that several transcription factors—TTF-1/NKX-2.1, TTF-2 (also termed FOXE1), NKX2.5, and PAX8—are important in thyroid gland morphogenesis and differentiation, and possibly also in its caudal migration to its final location. These factors also bind to the promoters of thyroglobulin and thyroid peroxidase genes and so influence thyroid hormone production. Hypothalamic neurons synthesize thyrotropin-releasing hormone (TRH) by 6-8 wk, the pituitary portal vessel system begins development by 8-10 wk, and thyroid-stimulating hormone (TSH) secretion is evident by 12 wk of gestation. Maturation of the hypothalamic-pituitary-thyroid axis occurs over the second half of gestation, but normal feedback relationships are not mature until approximately 3 mo of postnatal life. Other transcription factors, including PROP-1 and Pit-1, are important for differentiation and growth of thyrotrophs, along with somatotrophs and lactotrophs.

THYROID PHYSIOLOGY

The main function of the thyroid gland is to synthesize T_4 and T_3. The only known physiologic role of iodine (or iodide [I^-] in its ionized form) is in the synthesis of these hormones; the recommended dietary allowance of iodine is 30 µg/kg/24 hr for infants, 90-120 µg/24 hr for children, and 150 µg/24 hr for adolescents and adults.

The median iodine intake in the United States decreased by approximately 50% between the 1970s (320 µg/L) and the 1990s (145 µg/L), but it now appears to have stabilized (2009-2010 = 144 µg/L). Whatever the chemical form ingested, iodine eventually reaches the thyroid gland as iodide. Thyroid tissue has an avidity for iodide and is able to trap (with a gradient of 100 : 1), transport, and concentrate it in the follicular lumen for synthesis of thyroid hormone. Entry of iodide from the circulation into the thyroid is carried out by the sodium–iodide symporter. Iodide diffuses across the cell to the apical membrane where it is transported into the colloid via pendrin.

Before trapped iodide can react with tyrosine, it must be oxidized; this reaction is catalyzed by **thyroidal peroxidase.** Dual oxidase maturation factor 2 **(DUOXA2)** is required to express **DUOX2** enzymatic activity, which is required for H_2O_2 generation, a crucial step in iodide oxidation. The thyroid cells produce **thyroglobulin**, a large globular glycoprotein with a molecular weight of approximately 660,000, containing approximately 120 tyrosine units. Iodination of tyrosine forms monoiodotyrosine and diiodotyrosine; 2 molecules of diiodotyrosine then couple to form 1 molecule of T_4, or 1 molecule of diiodotyrosine and 1 of monoiodotyrosine to form T_3. Once formed, hormones are stored as thyroglobulin in the lumen of the follicle (colloid) until ready to be delivered to the body cells. T_4 and T_3 are liberated from thyroglobulin by activation of proteases and peptidases.

The metabolic potency of T_3 is 3-4 times that of T_4. In adults, the thyroid produces approximately 100 µg of T_4 and 20 µg of T_3 daily. Only 20% of circulating T_3 is secreted by the thyroid; the remainder is produced by deiodination of T_4 in the liver, kidney, and other extrathyroidal tissues by type I 5′-deiodinase. Selenocysteine is the active center of the iodothyronine deiodinases. Thus, selenium indirectly plays a role in normal growth and development. In the pituitary and brain, approximately 80% of required T_3 is produced locally from T_4 by a different enzyme, type II 5′-deiodinase. The level of T_3 in blood is one fiftieth that of T_4, but T_3 is the physiologically active thyroid hormone.

Thyroid hormones increase oxygen consumption, stimulate protein synthesis, influence growth and differentiation, and affect carbohydrate, lipid, and vitamin metabolism. Specific thyroid hormone transporters, of which the most important is monocarboxylate transporter 8, facilitate entry of T_4 and T_3 into cells. Once into the cell, T_4 is converted to T_3 by type I or II 5′-deiodinase. Intracellular T_3 then enters the nucleus, where it binds to thyroid hormone receptors. Thyroid hormone receptors are members of the steroid hormone receptor superfamily that includes glucocorticoids, estrogen, progesterone, vitamin D, and retinoids. Four different isoforms of the thyroid hormone receptor (α_1, α_2, β_1, and β_2) are expressed in different tissues; the protein product of the formerly designated c-*erb* A protooncogene *(THRA2)* is the α_2 thyroid hormone receptor in the brain and hypothalamus. Thyroid hormone receptors consist of a ligand-binding domain (binds T_3), hinge region, and DNA-binding domain (zinc finger). Binding of T_3 activates the thyroid hormone receptor response element, resulting in production of an encoded messenger RNA and protein synthesis specific for the target cell. In this manner, a single hormone, T_4, acting through tissue-specific thyroid hormone receptor isoforms and gene-specific thyroid response elements, can produce multiple effects in various tissues.

Approximately 70% of the circulating T_4 is firmly bound to T_4-binding globulin (TBG). Less-important carriers are T_4-binding prealbumin, called *transthyretin*, and albumin. Only 0.03% of T_4 in serum is not bound and comprises free T_4. Approximately 50% of circulating T_3 is bound to TBG, and 50% is bound to albumin; 0.30% of T_3 is unbound, or free, T_3. Because the concentration of TBG is altered in many clinical circumstances, its status must be considered when interpreting total T_4 or T_3 levels.

THYROID REGULATION

The thyroid is regulated by TSH, a glycoprotein produced and secreted by the anterior pituitary. This hormone activates adenylate cyclase in the thyroid gland and is important in all steps of thyroid hormone biosynthesis, from trapping of iodine to release of thyroid hormones. TSH is composed of 2 noncovalently bound subunits (chains): α and β. The α subunit is common to luteinizing hormone, follicle-stimulating hormone, and chorionic gonadotropin; the specificity of each hormone is conferred by the β subunit. TSH synthesis and release are stimulated by TRH, which is synthesized in the hypothalamus and secreted into the pituitary. TRH is found in other parts of the brain besides the hypothalamus and in many other organs; aside from its endocrine function, it may be a neurotransmitter. TRH is a simple tripeptide. In states of decreased production of thyroid hormone, TSH and TRH are increased. Exogenous thyroid hormone or increased thyroid hormone synthesis inhibits TSH and TRH production. Except in the neonate, levels of TRH in serum are very low.

Further control of the level of circulating thyroid hormones occurs in the periphery. In many nonthyroidal illnesses, extrathyroidal production of T_3 decreases; factors that inhibit T_4-type I 5′-deiodinase include fasting, chronic malnutrition, acute illness, and certain drugs. Such factors increase type III 5′-deiodinase conversion of T_4 to reverse T_3. Whereas levels of T_3 may be significantly decreased, levels of free

T_4 and TSH may remain normal. The decreased levels of T_3 may be a physiologic adaptation, resulting in decreased rates of oxygen production, of substrate use, and of other catabolic processes.

563.1 Thyroid Hormone Studies

Stephen H. LaFranchi

SERUM THYROID HORMONES

Methods are available to measure all the thyroid hormones in serum: T_4, free T_4, T_3, and free T_3. A metabolically inert T_3 (3,5′,3′-triiodothyronine), called reverse T_3, is also present in serum. Age must be considered in interpreting results, particularly in the neonate.

Thyroglobulin is a glycoprotein that is secreted through the apical surface of the thyroid follicular cell into the colloid. Small amounts escape into the circulation and are measurable in serum. Levels increase with TSH (also called *thyrotropin*) stimulation and decrease with TSH suppression. Serum thyroglobulin levels are increased in the neonate, in patients with Graves disease and other forms of autoimmune thyroid disease, and in those with endemic goiter. The most marked elevations of thyroglobulin occur in patients with differentiated carcinoma of the thyroid. Athyreotic infants have markedly reduced levels of thyroglobulin in serum.

Serum TSH levels are the most accurate test of thyroid function. Serum TSH levels are elevated in primary hypothyroidism and suppressed in hyperthyroidism. After the neonatal period, normal levels of TSH are <6 mIU/L. With central (secondary) hypothyroidism, serum TSH may be subnormal, though often it is "inappropriately" in the normal range, despite a low serum T_4 or free T_4 level. TSH appears to be less biologically active in central hypothyroidism. These sensitive (third-generation) TSH assays obviate the need for TRH stimulation in the diagnosis of most patients with thyroid disorders.

FETAL AND NEWBORN THYROID

Fetal serum T_4 and free T_4 increase progressively from midgestation to approximately 11.5 µg/dL and 1.5 ng/dL, respectively, at term. Fetal levels of T_3 are low before 20 wk and then gradually increase to approximately 45 ng/dL at term. Reverse T_3 levels (inactive form of T_3), however, are high in the fetus (250 ng/dL at 30 wk) and decrease to 150 ng/dL at term. Serum levels of TSH gradually increase to 10 mU/L at term. Approximately one third of maternal T_4 crosses the placenta to the fetus. Maternal T_4 plays a role in fetal development, especially that of the brain, before the synthesis of fetal thyroid hormone begins. The fetus of a hypothyroid mother may be at risk for neurologic injury, and a hypothyroid fetus may be partially protected by maternal T_4 until delivery. The amount of T_4 that crosses the placenta is not sufficient to interfere with a diagnosis of congenital hypothyroidism in the neonate.

At birth, there is an acute release of TSH; peak serum concentrations reach 60 mU/L 30 min following delivery in full-term infants. A rapid decline occurs in the ensuing 24 hr and a more gradual decline over the next 5 days to <10 mIU/L. The acute increase in TSH produces a dramatic increase in levels of T_4 to approximately 16 µg/dL and of T_3 to approximately 300 ng/dL in about 4 hr. This T_3 seems largely derived from increased peripheral conversion of T_4 to T_3. T_4 levels gradually decrease during the 1st 2 wk of life to 12 µg/dL. T_3 levels decline during the 1st wk of life to levels below 200 ng/mL. Serum free T_4 levels are 0.9-2.3 ng/dL in infancy and decline to 0.7-1.8 ng/dL in childhood. Serum free T_3 concentrations are approximately 180-760 pg/dL in infancy and decline to 230-650 pg/dL in childhood. Reverse T_3 levels are maintained for 2 wk (200 ng/dL) and decrease by 4 wk to around 50 ng/dL. In preterm infants, changes in thyroid function after birth are qualitatively similar to but quantitatively smaller than in full-term infants. Serum T_4 and T_3 levels are decreased in proportion to gestational age and birthweight.

SERUM THYROXINE-BINDING GLOBULIN

The thyroid hormones are transported in plasma bound to TBG, a glycoprotein synthesized in the liver. Estimation of TBG levels is occasionally necessary because TBG is increased or decreased in a variety of clinical situations, with effects on the level of total T_4 and T_3. TBG binds approximately 70% of T_4 and 50% of T_3. TBG levels increase in pregnancy, in the newborn period, with hepatitis, and with administration of estrogens (oral contraceptives), selective estrogen receptor modulators, heroin or methadone, mitotane, 5-fluorouracil, and perphenazine, and they decrease with androgens, anabolic steroids, glucocorticoids, nicotinic acid, and L-asparaginase. These effects are the results of modulation of hepatic synthesis of TBG. TBG levels may be markedly decreased owing to decreased production with hepatocellular disease or loss in the gut with protein-losing enteropathies or in urine, as in the congenital nephrotic syndrome. Decreased or increased levels of TBG also occur as genetic traits (see Chapter 564).

Some drugs, in particular phenytoin, carbamazepine, furosemide, salicylates, nonsteroidal antiinflammatory drugs, and heparin, also inhibit binding of T_4 and T_3 to TBG. In addition, phenytoin and carbamazepine cause abnormalities of thyroid function tests by another mechanism. They stimulate hepatic cytochrome P450 degradation of T_4 and accelerate transport of T_4 into tissues.

IN VIVO RADIONUCLIDE STUDIES

Markedly improved direct tests of thyroid function have made radioiodine uptake studies less necessary. The iodine trapping or concentrating mechanism of the thyroid can be evaluated by measuring the uptake of radioactive isotope ^{123}I (half-life: 13 hr). The technology allows doses of radioiodine (0.1-0.5 mCi) that are only a fraction of those used with ^{131}I. Technetium (^{99m}Tc) is a particularly useful radioisotope for children because in contrast to iodine, it is trapped but not organified by the thyroid and has a half-life of only 6 hr. Thyroid scanning may be indicated to assess the presence of thyroid tissue in questions of thyroid dysgenesis and to detect ectopic thyroid tissue, and thyroid uptake may be indicated to evaluate possible "hot" thyroid nodules. Diagnostic studies should be performed with ^{99m}Tc pertechnetate or ^{123}I because they have the advantages of lower radiation exposure and high-quality scintigrams. Radioiodine treatment, which may be used to treat children with Graves hyperthyroidism or differentiated thyroid cancer, employs administration of ^{131}I, which has a longer half-life (8 days) and greater killing effect.

THYROID ULTRASONOGRAPHIC STUDIES

Thyroid ultrasound examinations can determine the location, size, and shape of the thyroid gland, and they are useful for assessing the solid or cystic nature of nodules. Ultrasound is not as reliable as radionuclide studies in evaluating infants with suspected thyroid dysgenesis, particularly ectopic glands. Ultrasound examinations are useful in identifying normal thyroid gland position in children with suspected thyroglossal duct cysts. In children with autoimmune thyroiditis, ultrasound reveals scattered hypoechogenicity. Ultrasound examinations are more accurate than physical examination in estimating goiter size and assessing thyroid nodules. Certain characteristics of thyroid nodules, such as blurred margins, microcalcifications, hypoechogenicity, taller-than-wide shape, capsular extension, and increased vascularity, increase the likelihood of thyroid cancer, although none of these features is 100% sensitive or specific.

Chapter **564**

Defects of Thyroxine-Binding Globulin

Stephen H. LaFranchi and Stephen A. Huang

Abnormalities in levels of thyroxine-binding globulin (TBG) are not associated with clinical disease and do not require treatment. They are usually uncovered by a chance finding of abnormally low or high levels of thyroxine (T_4) and may be a source of confusion in the diagnosis of hypothyroidism or hyperthyroidism.

TBG deficiency occurs as an X-linked dominant disorder. Congenital TBG deficiency is most often discovered through screening programs for neonatal hypothyroidism that measure levels of T_4 as the primary screening test. Affected patients have low levels of total T_4 and elevated resin triiodothyronine uptake, but levels of free T_4 and thyroid-stimulating hormone are normal. The diagnosis is confirmed by the finding of absent or low levels of TBG. TBG deficiency occurs in 1 in 2,400 male newborns, 36% of whom have TBG levels <1 mg/dL. Milder forms of TBG deficiency occur in approximately 1 in 42,000 heterozygous female newborns. Complete TBG deficiency (<5 µg/dL) occurs much less often. To date, more than 25 different mutations have been reported in the TBG gene, resulting in either decreased TBG levels or reduced affinity of TBG for T_4. Table 564-1 lists causes of acquired TBG deficiency.

TBG excess also is a harmless X-linked dominant anomaly, occurring in approximately 1 in 25,000 persons. It has been recognized primarily in adults, but newborn screening programs may uncover the condition in the neonate. The level of T_4 is elevated, triiodothyronine is variably elevated, thyroid-stimulating hormone and free T_4 are normal, and resin triiodothyronine uptake is decreased. The elevated levels of TBG confirm the diagnosis. In affected neonates, levels of T_4 as high as 95 µg/dL have been found, which decrease to 20-30 µg/dL after 2-3 wk. Such high levels of T_4 may be related in part to the normally elevated levels of TBG in neonates, presumably as an effect of maternal estrogens. Affected patients are euthyroid. Family studies may be indicated to alert other affected family members. Table 564-1 lists causes of acquired TBG excess.

Familial dysalbuminemic hyperthyroxinemia is an autosomal dominant disorder that may be confused with hyperthyroidism. Markedly increased binding of T_4 to an abnormal albumin variant leads to increased serum concentrations of T_4. However, the levels of free T_4, free triiodothyronine, and thyroid-stimulating hormone are normal. Levels of triiodothyronine are normal or only slightly elevated. Affected patients are euthyroid.

Table 564-1 Causes of Acquired Thyroxine-Binding Globulin (TBG) Deficiency and Excess

DECREASED TBG	INCREASED TBG
Androgens	Estrogens
Anabolic steroids	Selective estrogen receptor modulators
Glucocorticoids	Pregnancy
Hepatocellular disease	Hepatitis
Severe illness	Porphyria
Protein-losing nephropathies	Heroin, methadone
Protein-losing enteropathies	Mitotane
Nicotinic acid	5-Flurouracil
L-Asparaginase	Perphenazine

Chapter 565

Hypothyroidism

Stephen H. LaFranchi and Stephen A. Huang

Hypothyroidism results from deficient production of thyroid hormone, either from a defect in the gland itself (primary hypothyroidism) or a result of reduced thyroid-stimulating hormone (TSH) stimulation (central or hypopituitary hypothyroidism; Table 565-1). The disorder may be manifested from birth (congenital) or acquired. When symptoms appear after a period of apparently normal thyroid function, the disorder may be truly acquired or might only appear so as a result of one of a variety of congenital defects in which the manifestation of the deficiency is delayed.

CONGENITAL HYPOTHYROIDISM

Most cases of congenital hypothyroidism are not hereditary and result from thyroid dysgenesis. Some cases are familial; these are usually caused by one of the inborn errors of thyroid hormone synthesis (dyshormonogenesis) and may be associated with a goiter. Most infants with congenital hypothyroidism are detected by newborn screening programs in the 1st few wk after birth, before obvious clinical symptoms and signs develop. In infants born in areas with no screening program, severe cases manifest features in the 1st few wk of life, but in cases of milder deficiency, manifestations may be delayed for months.

Epidemiology

The prevalence of congenital hypothyroidism based on nationwide programs for neonatal screening was initially reported at 1 in 4,000 infants worldwide. Over the last 2 decades, the prevalence has dropped to 1 in 2,000, likely the result of detection of milder cases of hypothyroidism. Studies from the United States report that the prevalence is lower in black Americans and higher in Asian-Americans and Pacific Islanders, Hispanics, and Native Americans as compared to white babies.

Etiology

See Table 565-1.

Primary Hypothyroidism

Thyroid Dysgenesis. Some form of thyroid dysgenesis (aplasia, hypoplasia, or an ectopic gland) is the most common cause of permanent congenital hypothyroidism, accounting for 80-85% of cases. In approximately 33% of cases of dysgenesis, even sensitive radionuclide scans can find no remnants of thyroid tissue (aplasia). In the other 66% of infants, rudiments of thyroid tissue are found in an ectopic location, anywhere from the base of the tongue (lingual thyroid) to the normal position in the neck (hypoplasia). Thyroid dysgenesis has a 2 : 1 female : male ratio.

The cause of thyroid dysgenesis is unknown in most cases. Thyroid dysgenesis occurs sporadically, but familial cases occasionally have been reported. The finding that thyroid developmental anomalies, such as thyroglossal duct cysts and hemiagenesis, are present in 8-10% of 1st-degree relatives of infants with thyroid dysgenesis supports an underlying genetic component.

Mutations in several transcription factors important for thyroid morphogenesis and differentiation (including TTF-1/NKX2.1, TTF-2 [also termed FOXE1], and PAX8) are monogenic causes of approximately 2% of the cases of thyroid dysgenesis. In addition, genetic

Table 565-1 Etiologic Classification of Congenital Hypothyroidism

PRIMARY HYPOTHYROIDISM
Defect of fetal thyroid development (dysgenesis)
- Aplasia
- Hypoplasia
- Ectopia

Defect in thyroid hormone synthesis (dyshormonogenesis)
- Iodide transport defect from blood into follicular cell: mutation in sodium–iodide symporter gene
- Defective iodide transport from follicular cell into colloid: mutation in Pendrin transport protein
- Thyroid organification, or coupling defect: mutation in thyroid peroxidase gene
- Defects in H_2O_2 generation: mutations in DUOXA2 maturation factor or *DUOX2* gene
- Thyroglobulin synthesis defect: mutation in thyroglobulin gene
- Deiodination defect: mutation in *DEHAL1* gene

TSH unresponsiveness
- Mutation in TSH receptor
- Defective TSH signaling: $G_s\alpha$ mutation (e.g., type IA pseudohypoparathyroidism)

Defect in thyroid hormone transport: mutation in monocarboxylate transporter 8 *(MCT8)* gene
Resistance to thyroid hormone
Maternal antibodies: thyrotropin receptor–blocking antibody (TRBAb, measured as *thyrotropin-binding inhibitor immunoglobulin*)
Iodine deficiency (endemic goiter)
Maternal medications
- Iodides, amiodarone
- Propylthiouracil, methimazole
- Radioiodine

CENTRAL (HYPOPITUITARY) HYPOTHYROIDISM
Isolated TSH deficiency: mutation in TSH β-subunit gene (depending on mutation, TSH may be undetectable, measurable ["normal"], or elevated)
Isolated TRH deficiency: mutation in TRH gene
TRH unresponsiveness: mutation in TRH receptor gene
Multiple congenital pituitary hormone deficiencies (e.g., septooptic dysplasia)
PIT-1 mutations
- Deficiency of TSH
- Deficiency of growth hormone
- Deficiency of prolactin

PROP-1 mutations
- Deficiency of TSH
- Deficiency of growth hormone
- Deficiency of prolactin
- Deficiency of LH
- Deficiency of FSH
- ±Deficiency of ACTH

ACTH, adrenocorticotropic hormone; FSH, follicle-stimulating hormone; LH, luteinizing hormone; TRH, thyroid-releasing hormone; TSH, thyroid-stimulating hormone.

defects leading to absent or ineffective thyrotropin (TSH) receptor binding or signaling have been described.

The transcription factor TTF-1/NKX2.1 is expressed in the thyroid, lung, and central nervous system. Mutations in TTF-1/NKX2.1 are reported to result in congenital hypothyroidism, respiratory distress, and persistent neurologic problems, including chorea and ataxia, despite early thyroid hormone treatment. NKX2.5 is expressed in the thyroid and heart. Mutations in *NKX2.5* are associated with congenital hypothyroidism and cardiac malformations. PAX-8 is expressed in the thyroid and kidney. Mutations in *PAX-8* are associated with congenital hypothyroidism and kidney and ureteral malformations.

The common finding of thyroid dysgenesis confined to only 1 of a pair of monozygotic twins suggests the operation of a deleterious factor during intrauterine life. Maternal antithyroid antibodies might be that factor. Although thyroid peroxidase antibodies have been detected in some mother–infant pairs, there is little evidence of their pathogenicity. The demonstration of thyroid growth-blocking and cytotoxic antibodies in some infants with thyroid dysgenesis, as well as in their mothers, suggests a more likely pathogenetic mechanism.

Defective Synthesis of Thyroxine (Dyshormonogenesis). A variety of defects in the biosynthesis of thyroid hormone can result in congenital hypothyroidism; these account for 15% of cases detected by neonatal screening programs (1 in 30,000-50,000 live births). These defects are transmitted in an autosomal recessive manner. A **goiter** is almost always present. When the defect is incomplete, compensation occurs, and onset of hypothyroidism may be delayed for years.

Defect of Iodide Transport. Defect of iodide transport is rare and involves mutations in the sodium–iodide symporter. Among the several cases now reported, it has been found in 9 related infants of the Hutterite sect, and approximately 50% of the cases are from Japan. Consanguinity is a factor in approximately 30% of the families.

In the past, clinical hypothyroidism, with or without a goiter, often developed in the 1st few months of life; the condition has been detected in neonatal screening programs. In Japan, however, untreated patients acquire goiter and hypothyroidism after 10 yr of age, perhaps because of the very high iodine content (often 19 mg/24 hr) of the Japanese diet.

The energy-dependent mechanisms for concentrating iodide are defective in the thyroid and salivary glands. In contrast to other defects of thyroid hormone synthesis, uptake of radioiodine and pertechnetate is low; a reduced saliva : serum ratio of ^{123}I will support the diagnosis, confirmed by finding a mutation in the sodium–iodide symporter gene. This condition responds to treatment with large doses of potassium iodide, but treatment with L-thyroxine is preferable.

Thyroid Peroxidase Defects of Organification and Coupling. Thyroid peroxidase defects of organification and coupling are the most common of the thyroxine (T_4) synthetic defects. After iodide is trapped by the thyroid, it is rapidly oxidized to reactive iodine, which is then incorporated into tyrosine units on thyroglobulin. This process requires generation of H_2O_2, thyroid peroxidase, and hematin (an enzyme cofactor); defects can involve each of these components, and there is considerable clinical and biochemical heterogeneity. In the Dutch neonatal screening program, 23 infants were found with a complete organification defect (1 in 60,000 live births), but its prevalence in other areas is unknown. A characteristic finding in all patients with this defect is a marked "discharge" of thyroid radioactivity when perchlorate or thiocyanate is administered 2 hr after administration of a test dose of radioiodine. In these patients, perchlorate discharges 40-90% of radioiodine compared with <10% in normal persons. Several mutations in the thyroid peroxidase gene have been reported in children with congenital hypothyroidism.

Dual oxidase maturation factor 2 **(DUOXA2)** is required to express **DUOX2** enzymatic activity, which is required for H_2O_2 generation, a crucial step in iodide oxidation. Biallelic *DUOXA2* mutations produce permanent congenital hypothyroidism, whereas monoallelic mutations are associated with transient hypothyroidism. *DUOX2* mutations can also cause permanent or transient congenital hypothyroidism. *DUOX2* mutations are relatively common, present in 30% of cases of apparent dyshormonogenesis, whereas *DUOXA2* mutations are relatively rare, present in 2% of such cases.

Pendred syndrome is an autosomal recessive disorder caused by a mutation in the chloride–iodide transport protein common to the thyroid gland and the cochlea. Pendred syndrome is comprised of sensorineural deafness and goiter; it is the most common cause of syndromic deafness. Pendrin allows transport of iodide from the follicular cell into the colloid where it undergoes organification to iodine and incorporation into the tyrosine residues on thyroglobulin. Patients with a mutation in the pendrin gene have impaired iodide organification and a positive perchlorate discharge.

Defects of Thyroglobulin Synthesis. Defects of thyroglobulin synthesis are a heterogeneous group of disorders characterized by goiter, elevated serum TSH, low T_4 levels, and absent or low levels of thyroglobulin. It has been reported in approximately 100 patients. Molecular defects, primarily point mutations, have been described in several patients.

Defects in Deiodination. Monoiodotyrosine and diiodotyrosine released from thyroglobulin are normally deiodinated within the thyroid or in peripheral tissues by a deiodinase. The liberated iodine is recycled in the synthesis of thyroid hormones. The *DEHAL1* gene encodes iodotyrosine deiodinase in the thyroid. *DEHAL1* mutations are relatively rare; patients with deiodinase deficiency experience severe iodine loss from the constant urinary excretion of nondeiodinated tyrosines, leading to hormonal deficiency and goiter. The deiodination defect may be limited to thyroid tissue only or to peripheral tissue only, or it may be universal.

Thyrotropin Hormone Unresponsiveness. A mutation in the TSH receptor gene is a relatively uncommon autosomal recessive cause of congenital hypothyroidism. Both homozygous and compound heterozygous mutations in the TSH receptor gene have been reported. Infants with a severe defect have elevated TSH levels and will be detected by newborn screening, whereas other patients with a mild defect remain euthyroid without treatment. A study of infants with congenital hypothyroidism detected by newborn screening from Tokyo reported TSH receptor mutations in 4.3% of patients (1 in 118,000 live births), with a founder mutation (p.R450H) accounting for 70% of gene defects.

Mild congenital hypothyroidism has been detected in newborn infants who subsequently proved to have **type Ia pseudohypoparathyroidism.** The molecular cause of resistance to TSH in these patients is the generalized impairment of cyclic adenosine monophosphate activation caused by genetic defect of the α subunit of the guanine nucleotide regulatory protein G_s (see Chapter 572).

Defects in Thyroid Hormone Transport. Passage of thyroid hormone into the cell is facilitated by plasma membrane transporters. A mutation in one such transporter gene, monocarboxylate transporter 8 *(MCT8)*, located on the X chromosome **(Allan-Herndon-Dudley syndrome),** has now been reported in multiple patients. The defective transporter impairs passage of T_4 and triiodothyronine (T_3) into cells; this syndrome is characterized by elevated serum T_3 levels, low T_4 levels, and normal or mildly elevated TSH levels. Neurologic manifestations include severe developmental delay, reduced muscle mass, initial hypotonia that evolves into spastic paraplegia, dysarthria, and athetoid movements.

Resistance to Thyroid Hormone

This autosomal dominant disorder is caused by mutations in the thyroid hormone receptor. Most patients have a goiter, and levels of T_4, T_3, free T_4, and free T_3 are elevated. These findings often have led to the erroneous diagnosis of Graves disease, although most affected patients are clinically euthyroid. The unresponsiveness can vary among tissues. There may be subtle clinical features of hypothyroidism, including developmental delay, growth retardation, and delayed skeletal maturation. On the other hand, there may be clinical features compatible with hyperthyroidism, such as tachycardia and hyperreflexia. It is presumed that these patients have varying tissue resistance to thyroid hormone. One neurologic manifestation is an increased association of attention-deficit/hyperactivity disorder; the converse is not true because patients with attention-deficit/hyperactivity disorder do not have an increased risk of thyroid hormone resistance.

TSH levels are diagnostic in that they are not suppressed as in Graves disease but instead are moderately elevated or normal but inappropriate for the levels of T_4 and T_3. The failure of TSH suppression indicates that the resistance is generalized and affects the pituitary gland as well as peripheral tissues. More than 40 distinct point mutations in the hormone-binding domain of the β-thyroid receptor are identified. Different phenotypes do not correlate with genotypes. The same mutation has been observed in patients with generalized or isolated pituitary resistance, even in different members of the same family. A child homozygous for the receptor mutation showed unusually severe resistance. These cases support the dominant negative effect of mutant receptors, in which the mutant receptor protein inhibits normal receptor action in heterozygotes. Elevated levels of T_4 on neonatal thyroid screening should suggest the possibility of this diagnosis. No treatment is usually required unless growth and skeletal retardation are present.

Two infants of consanguineous matings are known to have an autosomal recessive form of thyroid resistance. These infants had manifestations of hypothyroidism early in life, and genetic studies revealed a major deletion of the β-thyroid receptor in 1 of them. The resistance appears to be more severe in this form of the entity.

Some patients have greater resistance to thyroid hormone in the pituitary gland as compared to peripheral tissues. Because the peripheral tissues are not resistant to thyroid hormones, the patient has a goiter and manifestations of hyperthyroidism. The laboratory findings are the same as those seen with generalized thyroid hormone resistance. This condition must be differentiated from a pituitary TSH-secreting tumor. Different treatments, including D-thyroxine, triiodothyroacetic acid, and tetraiodothyroacetic acid, have been successful in some patients. Bromocriptine administration, which interferes with TSH secretion, was reported to be successful in another patient. Whether isolated pituitary resistance to thyroid hormone exists as a distinct entity is controversial; it may be a variant of generalized resistance to thyroid hormone with varying tissue responsiveness.

Although the majority of patients with resistance have mutations in the thyroid hormone receptor β gene, a child with a mutation in the thyroid hormone receptor α gene has been reported. This patient presented at age 6 yr with growth retardation, delayed development, and constipation. Genetic analysis showed a heterozygous nonsense mutation in the thyroid hormone receptor α gene that, like β gene mutations, inhibited wild-type receptor action in a dominant negative manner.

Thyrotropin Receptor-Blocking Antibody. Maternal TSH receptor-blocking antibody (TRBAb) is an unusual cause of transitory congenital hypothyroidism. Transplacental passage of maternal TRBAb inhibits binding of TSH to its receptor in the neonate. Maternal TRBAb accounts for 2% of cases detected by neonatal screening programs (1 in 50,000-100,000 infants). It should be suspected whenever there is a history of maternal autoimmune thyroid disease, including Hashimoto thyroiditis or Graves disease, maternal hypothyroidism on replacement therapy, or recurrent congenital hypothyroidism of a transient nature in previous siblings. In these situations, maternal levels of TRBAb (measured as thyrotropin-binding inhibitor immunoglobulin) should be determined during pregnancy. Affected infants and their mothers also can have thyrotropin receptor–stimulating antibodies and thyroid peroxidase antibodies. Technetium pertechnetate and ^{123}I scans might fail to detect any thyroid tissue, mimicking thyroid agenesis, but ultrasonography will show a thyroid gland. After the condition remits, a normal thyroid gland is demonstrable by scanning following discontinuation of replacement therapy. The half-life of the antibody is 21 days, and remission of the hypothyroidism occurs in approximately 3-6 mo. Correct diagnosis of this cause of congenital hypothyroidism prevents unnecessary protracted treatment, alerts the clinician to possible recurrences in future pregnancies, and allows a favorable prognosis.

Radioiodine Administration. Hypothyroidism can occur as a result of inadvertent administration of radioiodine during pregnancy for treatment of Graves disease or cancer of the thyroid. The fetal thyroid is capable of trapping iodide by 70-75 days of gestation. Whenever radioiodine is administered to a woman of childbearing age, a pregnancy test must be performed before a therapeutic dose of ^{131}I is given, regardless of the menstrual history or putative history of contraception. Administration of radioactive iodine to lactating women also is contraindicated because it is readily excreted in milk.

Iodine Exposure. Congenital hypothyroidism can result from fetal exposure to excessive iodides. Perinatal exposure can occur with the use of iodine antiseptic to prepare the skin for caesarian section or painting of the cervix before delivery. It has also been reported in infants born to mothers who consumed large amounts of iodine daily (up to 12 mg) in the form of nutritional supplements and in mothers in Japan who consumed large quantities of iodine-rich seaweed. These conditions are transitory and must not be mistaken for the other forms of hypothyroidism. In the neonate, topical iodine-containing antiseptics used in nurseries and by surgeons can also cause transient congenital hypothyroidism, especially in low-birthweight infants, and can

lead to abnormal results on neonatal screening tests. In older children, the usual sources of iodides are proprietary preparations used to treat asthma. In a few instances, the cause of hypothyroidism was amiodarone, an antiarrhythmic drug with high iodine content. In most of these instances, goiter is present (see Chapter 567).

Iodine-Deficiency Endemic Goiter. See Chapter 567.3.

Iodine deficiency or endemic goiter is the most common cause of congenital hypothyroidism worldwide. The recommended intake of iodine in adults is 150 μg daily, increasing to 250 μg daily during pregnancy to allow for fetal iodine requirements. Despite efforts at universal iodization of salt in many countries, economic, political, and practical obstacles make achieving this objective difficult. While the U.S. population is iodine-sufficient as a whole, approximately 15% of women of reproductive age fall into the iodine-deficient category. Borderline iodine deficiency is more likely to cause problems in preterm infants who depend on a maternal source of iodine for normal thyroid hormone production.

Central (Hypopituitary) Hypothyroidism

Thyrotropin and Thyrotropin-Releasing Hormone Deficiency. Deficiency of TSH and central hypothyroidism can occur in any of the conditions associated with developmental defects of the pituitary or hypothalamus (see Chapter 557). More often in these conditions, the deficiency of TSH is secondary to a deficiency of thyrotropin-releasing hormone (TRH). TSH-deficient hypothyroidism is found in 1 in 30,000-50,000 infants; most screening programs are designed to detect primary hypothyroidism, so most of these cases are not detected by neonatal thyroid screening. The majority of affected infants have multiple pituitary deficiencies and present with hypoglycemia, persistent jaundice, and micropenis in association with septooptic dysplasia, midline cleft lip, midface hypoplasia, and other midline facial anomalies.

Mutations in genes coding for transcription factors essential to pituitary development, cell type differentiation, and hormone synthesis are associated with congenital TSH deficiency. *PIT-1* mutations include TSH deficiency associated with growth hormone and prolactin deficiency. Patients with *PROP-1* mutations ("prophet of pit-1") have not only TSH, growth hormone, and prolactin deficiency but also luteinizing hormone and follicle-stimulating hormone deficiency and variable adrenocorticotropic hormone deficiency. *HESX1* mutations are associated with TSH, growth hormone, prolactin, and adrenocorticotropic hormone deficiencies and are found in some patients with optic nerve hypoplasia (septooptic dysplasia syndrome; see Chapter 591).

Isolated deficiency of TSH is a rare autosomal recessive disorder that has been reported in several sibships. DNA studies in affected family members reveal defects in the TSH β-subunit gene, including point mutations, frame shifts causing a stop codon, and splice-site mutations. Depending on the specific mutation, serum TSH levels may be undetectable, measureable, or elevated. The diagnosis is usually delayed because the serum TSH level is not elevated in most cases, and so such patients are not detected by newborn screening programs.

Thyrotropin-Releasing Hormone Receptor Abnormality. Mutations in the TRH receptor gene, a rare cause of congenital central hypothyroidism, have now been reported in a few families. This condition, which results in isolated TSH deficiency and hypothyroidism, was suspected because of failure of both TSH and prolactin to respond to TRH stimulation.

Thyroid Function in Preterm Babies

Postnatal thyroid function in preterm babies is qualitatively similar but quantitatively reduced compared with that of term infants. The cord serum T_4 is decreased in proportion to gestational age and birthweight. The postnatal TSH surge is reduced, and the more premature, very-low-birthweight infants with complications of prematurity, such as respiratory distress syndrome, actually experience a decrease in serum T_4 in the 1st wk of life. As these complications resolve, the serum T_4 gradually increases so that generally by 6 wk of life it enters the T_4 range seen in term infants. Serum free T_4 concentrations seem less affected, and when measured by equilibrium dialysis, these levels are often normal. Preterm babies also have a higher incidence of "delayed" TSH elevation and apparent transient primary hypothyroidism. Premature infants of <28 wk of gestation might have problems resulting from a combination of immaturity of the hypothalamic-pituitary-thyroid axis and loss of the maternal contribution of thyroid hormone and so may be candidates for temporary thyroid hormone replacement; further studies are needed.

Clinical Manifestations

Most infants with congenital hypothyroidism are asymptomatic at birth, even if there is complete agenesis of the thyroid gland. This situation is attributed to partial transplacental passage of maternal T_4, which provides fetal levels that are approximately 33% of normal at birth. Despite this maternal contribution of T_4, hypothyroid infants still have a low serum T_4 and elevated TSH level and so will be identified by newborn screening programs.

The clinician depends on neonatal screening tests for the diagnosis of congenital hypothyroidism. Some babies escape newborn screening, and laboratory errors occur, so awareness of early symptoms and signs must be maintained. Congenital hypothyroidism caused by thyroid dysgenesis, the most common etiology, is twice as common in girls as in boys. Before neonatal screening programs, congenital hypothyroidism was rarely recognized in the newborn because the signs and symptoms are usually not sufficiently developed. It can be suspected and the diagnosis established during the early weeks of life if the initial, but less characteristic, manifestations are recognized. Birthweight and length are normal, but head size may be slightly increased because of myxedema of the brain. The anterior and posterior fontanels are open widely; observation of this sign at birth can serve as an initial clue to the early recognition of congenital hypothyroidism. *Only 3% of normal newborn infants have a posterior fontanel larger than 0.5 cm*. Prolongation of physiologic jaundice, caused by delayed maturation of glucuronide conjugation, may be the earliest sign. Feeding difficulties, especially sluggishness, lack of interest, somnolence, and choking spells during nursing, are often present during the 1st mo of life. Respiratory difficulties, partly caused by the large tongue, include apneic episodes, noisy respirations, and nasal obstruction. Some infants may develop respiratory distress syndrome. Affected infants cry little, sleep much, have poor appetites, and are generally sluggish. There may be constipation that does not usually respond to treatment. The abdomen is large, and an umbilical hernia is usually present. The temperature is subnormal, often <35°C (95°F), and the skin, particularly that of the extremities, may be cold and mottled. Edema of the genitals and extremities may be present. The pulse is slow, and heart murmurs, cardiomegaly, and asymptomatic pericardial effusion are common. Macrocytic anemia is often present and is refractory to treatment with hematinics. Because symptoms appear gradually, the clinical diagnosis is often delayed.

Approximately 10% of infants with congenital hypothyroidism have associated congenital anomalies. Cardiac anomalies are most common, but anomalies of the nervous system and eye have also been reported. Infants with congenital hypothyroidism may have associated hearing loss. As noted under "Etiology" above, specific mutations in genes involved in thyroid gland development result in "syndromic" congenital hypothyroidism. Mutations in *NKX2.1 (TTF-1)*, present in the thyroid gland, lungs, and brain, are characterized by congenital hypothyroidism, respiratory distress syndrome, and ataxia, or even choreoathetosis. Mutations in *NKX2.5* result in congenital hypothyroidism and associated congenital heart defects. Mutations in *TTF-2*, present in the thyroid gland, palate, and hair, include congenital hypothyroidism, cleft palate, and spiky hair. Mutations in *PAX-8*, present in the thyroid gland and kidneys, present with congenital hypothyroidism and genitourinary anomalies, including renal agenesis.

If congenital hypothyroidism goes undetected and untreated, these manifestations progress. Retardation of physical and mental development becomes greater during the following months, and by 3-6 mo of age the clinical picture is fully developed (Fig. 565-1). When there is only partial deficiency of thyroid hormone, the symptoms may be milder, the syndrome incomplete, and the onset delayed. Although breast milk contains significant amounts of thyroid hormones,

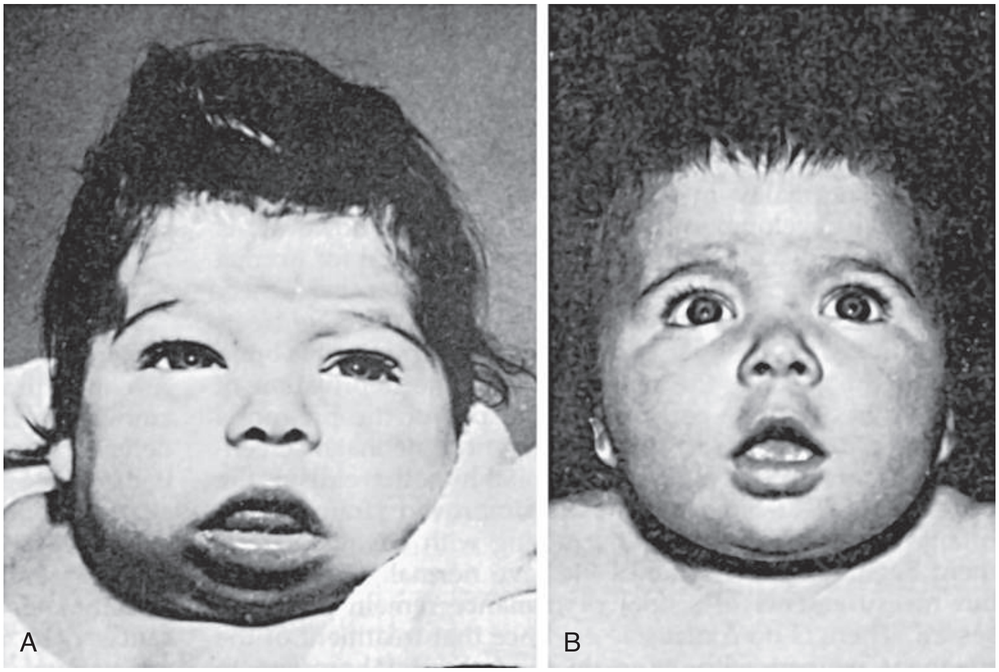

Figure 565-1 Congenital hypothyroidism in an infant 6 mo of age. The infant ate poorly in the neonatal period and was constipated. She had a persistent nasal discharge and a large tongue; she was very lethargic and had no social smile and no head control. **A,** Notice the puffy face, dull expression, and hirsute forehead. Tests revealed a negligible uptake of radioiodine. Osseous development was that of a newborn. **B,** Four mo after treatment, note the decreased puffiness of the face, the decreased hirsutism of the forehead, and the alert appearance.

particularly T_3, it is inadequate to protect the breastfed infant who has congenital hypothyroidism, and it has no effect on neonatal thyroid screening tests.

The child's growth will be stunted, the extremities are short, and the head size is normal or even increased. The anterior fontanel is large and the posterior fontanel may remain open. The eyes appear far apart, and the bridge of the broad nose is depressed. The palpebral fissures are narrow and the eyelids are swollen. The mouth is kept open, and the thick, broad tongue protrudes. Dentition will be delayed. The neck is short and thick, and there may be deposits of fat above the clavicles and between the neck and shoulders. The hands are broad and the fingers are short. The skin is dry and scaly, and there is little perspiration. Myxedema is manifested, particularly in the skin of the eyelids, the back of the hands, and the external genitals. The skin shows general pallor with a sallow complexion. Carotenemia can cause a yellow discoloration of the skin, but the sclerae remain white. The scalp is thickened, and the hair is coarse, brittle, and scanty. The hairline reaches far down on the forehead, which usually appears wrinkled, especially when the infant cries.

Development is usually delayed. Hypothyroid infants appear lethargic and are late in learning to sit and stand. The voice is hoarse, and they do not learn to talk. The degree of physical and intellectual delay increases with age. Sexual maturation may also be delayed or might not take place at all.

The muscles are usually hypotonic, but in rare instances generalized muscular pseudohypertrophy occurs **(Kocher-Debré-Sémélaigne syndrome).** Affected older children can have an athletic appearance because of pseudohypertrophy, particularly in the calf muscles. Its pathogenesis is unknown; nonspecific histochemical and ultrastructural changes seen on muscle biopsy return to normal with treatment. Boys are more prone to development of the syndrome, which has been observed in siblings born from a consanguineous mating. Affected patients have hypothyroidism of longer duration and severity.

Some infants with mild congenital hypothyroidism have normal thyroid function at birth and so are not identified by newborn screening programs. In particular, some children with ectopic thyroid tissue (lingual, sublingual, subhyoid) produce adequate amounts of thyroid hormone for many years, or it eventually fails in early childhood. Affected children come to clinical attention because of a growing mass at the base of the tongue or in the midline of the neck, usually at the level of the hyoid. Occasionally, ectopia is associated with **thyroglossal duct cysts**. It can occur in siblings. Surgical removal of ectopic thyroid tissue from a euthyroid patient usually results in hypothyroidism, because most such patients have no other thyroid tissue.

Laboratory Findings

In developed countries, infants with congenital hypothyroidism are identified by newborn screening programs. Blood obtained by heelprick between 2 and 5 days of life is placed on a filter paper card and sent to a central screening laboratory. The early approach to newborn screening in North America and Europe began with measure of levels of T_4, followed by measurement of TSH when T_4 is low. This approach identifies infants with primary hypothyroidism, some with central or hypopituitary hypothyroidism, and infants with a delayed elevation in TSH levels. Over time, many neonatal screening programs in North America, Europe, and elsewhere in the world have switched to an initial TSH measurement. This approach will detect infants with primary hypothyroidism and infants with milder, subclinical hypothyroidism (normal T_4, elevated TSH), but it may not detect infants with delayed TSH elevation or with central or hypopituitary hypothyroidism. With any of these tests, special care should be given to the normal range of values for age of the patient, particularly in the 1st weeks of life (Table 565-2). Regardless of the approach used for screening, some infants escape detection because of technical or human errors; clinicians must maintain their vigilance for clinical manifestations of hypothyroidism.

Serum levels of T_4 or free T_4 are low; serum levels of T_3 may be normal and are not helpful in the diagnosis. If the defect is primarily in the thyroid, levels of TSH are elevated, often to >100 mU/L. Serum levels of thyroglobulin are usually low in infants with thyroid agenesis or defects of thyroglobulin synthesis or secretion, whereas they are elevated with ectopic glands and other inborn errors of T_4 synthesis, but there is a wide overlap of ranges.

Special attention should be paid to identical twins; in several reported cases, neonatal screening failed to detect the affected twin with hypothyroidism, and the diagnosis was not made until the infants were 4-5 mo of age. In these cases, transfusion of euthyroid blood from the unaffected twin normalized the serum levels of T_4 and TSH in the

Table 565-2 Thyroid Function Tests

AGE	U.S. REFERENCE VALUE	CONVERSION FACTOR	SI REFERENCE VALUE
THYROID THYROGLOBULIN, SERUM			
Cord blood	14.7-101.1 ng/mL	×1	14.7-101.1 μg/L
Birth to 35 mo	10.6-92.0 ng/mL	×1	10.6-92.0 μg/L

affected twin at the initial screening. Many newborn screening programs perform a routine second test in same-sex twins.

Retardation of osseous development can be shown radiographically at birth in approximately 60% of congenitally hypothyroid infants and indicates some deprivation of thyroid hormone during intrauterine life. The distal femoral and proximal tibial epiphyses, normally present at birth, are often absent (Fig. 565-2*A*). In undetected and untreated patients, the discrepancy between chronologic age and osseous development increases. The epiphyses often have multiple foci of ossification (epiphyseal dysgenesis; Fig. 565-2*B*); deformity

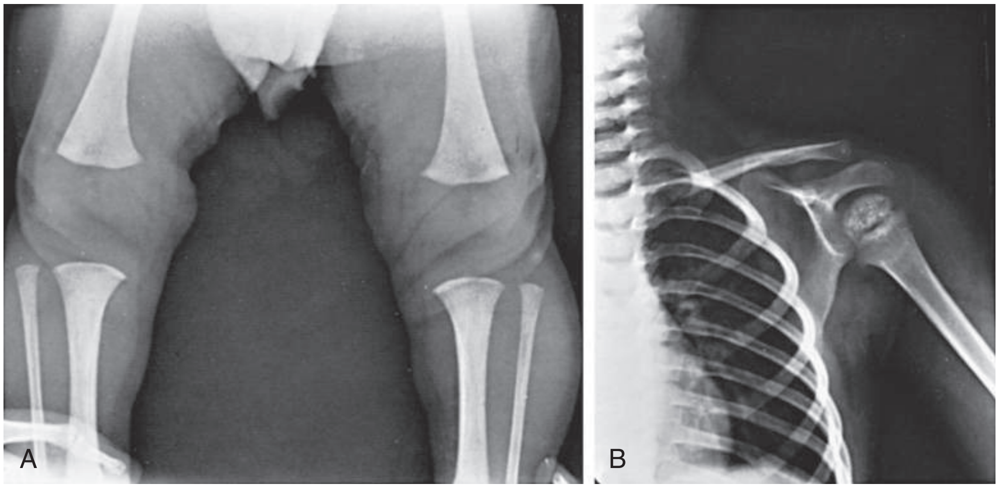

Figure 565-2 Congenital hypothyroidism. **A,** Absence of distal femoral epiphysis in a 3 mo old infant who was born at term. This is evidence for the onset of the hypothyroid state during fetal life. **B,** Epiphyseal dysgenesis in the head of the humerus in a 9 yr old girl who had been inadequately treated with thyroid hormone.

("beaking") of the 12th thoracic or 1st or 2nd lumbar vertebra is common. X-rays of the skull show large fontanels and wide sutures; intersutural (wormian) bones are common. The sella turcica is often enlarged and round; in rare instances, there may be erosion and thinning. Formation and eruption of teeth can be delayed. Cardiac enlargement or pericardial effusion may be present.

Scintigraphy can help to pinpoint the underlying cause in infants with congenital hypothyroidism, but treatment should not be unduly delayed for this study. ^{123}I-sodium iodide is superior to ^{99m}Tc-sodium pertechnetate for this purpose. Ultrasonographic examination of the thyroid is helpful, but studies show it can miss some ectopic glands shown by scintigraphy. Demonstration of ectopic thyroid tissue is diagnostic of thyroid dysgenesis and establishes the need for lifelong treatment with T_4. Failure to demonstrate any thyroid tissue suggests thyroid aplasia, but this also occurs in neonates with hypothyroidism caused by maternal TRBAb and in infants with the iodide-trapping defect. A normally situated thyroid gland with a normal or avid uptake of radionuclide indicates a defect in thyroid hormone biosynthesis. In the past, patients with goitrous hypothyroidism have required extensive evaluation, including radioiodine studies, perchlorate discharge tests, kinetic studies, chromatography, and studies of thyroid tissue, to determine the biochemical nature of the defect. Most can be evaluated by genetic studies looking for a suspected mutation in the steps along the T_4 biosynthetic pathway.

The electrocardiogram may show low-voltage P and T waves with diminished amplitude of QRS complexes and suggest poor left ventricular function and pericardial effusion. Echocardiography can confirm a pericardial effusion. The electroencephalogram often shows low voltage. In children older than 2 yr of age, the serum cholesterol level is usually elevated. Brain MRI before treatment is reportedly normal, although proton magnetic resonance spectroscopy shows high levels of choline-containing compounds, which can reflect blocks in myelin maturation.

Treatment

Levothyroxine (L-T_4) given orally is the treatment of choice. Although T_3 is the biologically active form of thyroid hormone, most of the T_3 in the brain is formed from local deiodination of T_4. Because 80% of circulating T_3 is formed by monodeiodination of T_4, serum levels of T_4 and T_3 return to normal with L-T_4 treatment alone. The recommended initial starting dose is 10-15 µg/kg/day (totaling 37.5-50.0 µg/day for most term infants). The starting dose can be tailored to the severity of hypothyroidism. Rapid normalization of thyroid function has been demonstrated to be important in achieving optimal neurodevelopmental outcome. Newborns with more severe hypothyroidism, as judged by a serum T_4 <5 µg/dL and/or imaging studies confirming aplasia, should be started at the higher end of the dosage range.

L-T_4 is available only in tablet form in the United States; there is an approved liquid L-T_4 preparation in Europe. The daily tablets should be crushed and mixed with a small volume of liquid. *L-T_4 tablets should not be mixed with soy protein formulas, concentrated iron, or calcium, because these can bind T_4 and inhibit its absorption*. Although it is recommended to administer L-T_4 on an empty stomach and avoid food for 30-60 min, this is not practical in an infant. As long as the method of administration is consistent day to day, dosing can be adjusted based on serum thyroid test results to achieve the desired treatment goals.

Levels of serum T_4 or free T_4 and TSH should be monitored at recommended intervals (every 1-2 mo in the 1st 6 mo of life, and then every 2-4 mo between 6 mo and 3 yr of age). The goals of treatment are to maintain the serum free T_4 or total T_4 in the upper half of the reference range for age (see Table 565-2), with serum TSH in the reference range for age, optimally 0.5-2.0 mU/L. The dose of L-T_4 on a weight basis gradually decreases with age.

Later, confirmation of the diagnosis may be necessary for some infants to rule out the possibility of transient hypothyroidism. This is unnecessary in infants with proven thyroid ectopia or in those who manifest elevated levels of TSH after 6-12 mo of therapy because of poor compliance or an inadequate dose of T_4. Discontinuation of therapy at about 3 yr of age for 3-4 wk results in a marked increase in TSH levels in children with permanent hypothyroidism.

Care should be taken to avoid prolonged undertreatment or overtreatment. The only untoward effects of L-T_4 are related to its dosage. Overtreatment can risk craniosynostosis and temperament problems.

Prognosis

Thyroid hormone is critical for normal cerebral development in the early postnatal months; biochemical diagnosis must be made soon after birth, and effective treatment must be initiated promptly to prevent irreversible brain damage. With the advent of neonatal screening programs for detection of congenital hypothyroidism, the prognosis for affected infants has improved dramatically. Early diagnosis and adequate treatment from the 1st weeks of life result in normal linear growth and development. Most studies report that psychometric testing in infants detected by newborn screening shows verbal, psychomotor, and global IQ scores similar to those of unaffected siblings or classmate controls. Some screening programs report that the most severely affected infants, as judged by the lowest T_4 levels and retarded skeletal maturation, have reduced IQs (by 5-20 points) and other neuropsychologic sequelae, such as incoordination, hypotonia or hypertonia, short attention span, and speech problems, even with early diagnosis and

adequate treatment. Psychometric testing can show problems with vocabulary and reading comprehension, arithmetic, and memory. Approximately 20% of children have a neurosensory hearing deficit. Outcome studies in adults, detected and treated as neonates, reveal delayed social development, lower self-esteem, and a lower health-related quality of life. The latter appears to be related to those individuals with lower neurocognitive outcome and associated congenital malformations.

Delay in diagnosis, failure to correct initial hypothyroxinemia rapidly, inadequate treatment, and poor compliance in the 1st 2-3 yr of life result in variable degrees of brain damage. Without treatment, affected infants are profoundly intellectually challenged and growth retarded. When onset of hypothyroidism occurs after 2 yr of age, the outlook for normal development is much better even if diagnosis and treatment have been delayed, indicating how much more important thyroid hormone is to the rapidly growing brain of the infant.

ACQUIRED HYPOTHYROIDISM

Epidemiology

Studies of school-age children report that hypothyroidism occurs in approximately 0.3% (1 in 333). Subclinical hypothyroidism (TSH >4.5 mU/L, normal T_4 or free T_4) is more common, occurring in approximately 2% of adolescents. Acquired hypothyroidism is most commonly a result of chronic lymphocytic thyroiditis; 6% of children age 12-19 yr have evidence of autoimmune thyroid disease, which occurs with a 2 : 1 female : male preponderance.

Etiology

The most common cause of acquired hypothyroidism (Table 565-3) is chronic lymphocytic (Hashimoto) thyroiditis (see Chapter 566). **Autoimmune thyroid disease** may be part of polyglandular syndromes; children with Down and Turner syndrome, possibly Klinefelter syndrome, and celiac disease or diabetes are at higher risk for associated autoimmune thyroid disease (see Chapter 566) as are those with **autoimmune polyglandular syndromes (APSs)** (Tables 565-4 and 565-5). APS has 4 types, but APS-1 and APS-2 are the most common. APS-1 includes 2 components of the triad of hypoparathyroidism, Addison disease (adrenal insufficiency) and mucocutaneous candidiasis ("HAM" syndrome). Commonly referred to by the acronym APECED (autoimmune polyendocrinopathy-candidiasis-ectodermal dysplasia), it is autosomal recessive, caused by a mutation in the *AIRE* (autoimmune regulator) gene. Less-common features include thyroiditis (~10%), type 1 diabetes mellitus, primary hypogonadism, pernicious anemia, vitiligo, alopecia, chronic active hepatitis, and malabsorption syndrome. APS-2 (Schmidt syndrome) most commonly consists of autoimmune thyroiditis (~70%), Addison disease, and type 1 diabetes mellitus. Less-common features include primary hypogonadism, pernicious anemia, and vitiligo. APS-2 occurs more commonly than APS-1, generally presents in early adulthood, and has a female preponderance. The underlying immunologic defect remains to be determined.

Table 565-4 Autoimmune Polyglandular Syndromes 1 and 2

	APS-1	APS-2
Incidence	<1 in 100,000 population/yr	1-2 in 10,000 population/yr
Onset	Infancy/early childhood	Late childhood/ adulthood
Male : female ratio	3 : 4	1 : 3
Inheritance	Monogenic (*AIRE* gene)	Polygenic (HLA-associated)
Mucocutaneous candidiasis	73-100%	None
Hypoparathyroidism	77-89%	None
Addison disease	60-86%	70-100%
Type 1 diabetes	4-18%	41-52%
Autoimmune thyroid disease	8-40%	70%
GONADAL FAILURE		
Male	7-17%	5%
Female	30-60%	3.5-10%
Ectodermal dysplasia	77%	None
Vitiligo	4-13%	4-5%
Pernicious anemia	12-15%	2-25%
Alopecia	27%	2%
Autoimmune hepatitis	10-15%	Rare
Malabsorption	10-18%	Rare

Table 565-3 Etiologic Classification of Acquired Hypothyroidism

Autoimmune
- Hashimoto thyroiditis
- Autoimmune polyglandular syndromes types 1 and 2 (APS-1, APS-2)

Drug-induced
- Excess iodide: amiodarone, nutritional supplements, expectorants
- Anticonvulsants: phenytoin, phenobarbital, valproate
- Antithyroid drugs: methimazole, propylthiouracil
- Miscellaneous: lithium, tyrosine kinase inhibitors, interferon alfa, stavudine, thalidomide, aminoglutethimide

Postablative
- Irradiation
- Radioiodine
- Thyroidectomy

Systemic infiltrative disease
- Cystinosis
- Langerhans cell histiocytosis

Hemangiomas (large) of the liver (type 3 iodothyronine deiodinase)

Hypothalamic-pituitary disease with multiple pituitary hormone deficiencies
- Hypothalamic-pituitary tumors (e.g., craniopharyngioma)
- Meningoencephalitis
- Cranial radiation
- Head trauma
- Langerhans cell histiocytosis

Table 565-5 Organ-Specific Autoantigens in Autoimmune Polyglandular Syndromes

DISEASE	AUTOANTIGENS
Addison disease	P450c21, P450c17, P450scc
Hashimoto thyroiditis	Thyroid peroxidase, thyroglobulin
Graves disease	TSH receptor
Hypoparathyroidism	Calcium-sensing receptor, NALP 5 (NACHT leucine-rich-repeat protein 5)
Type 1 diabetes	Insulin, glutamic acid decarboxylase-65, IA-2A, ZnT8
Hypogonadism	P450c17, P450scc
Immune gastritis	H+, K+-ATPase
Pernicious anemia	Intrinsic factor
Celiac disease	Transglutaminase, gliadin
Immune hepatitis	P450D6, P4502C9, P4501A2
Alopecia areata	Tyrosine hydroxylase
Vitiligo	Tyrosinase

ATPase, adenosine triphosphatase; TSH, thyroid-stimulating hormone.

From Nambam B, Winter WE, Schatz DA: IgG$_4$ antibodies in autoimmune polyglandular disease and IgG$_4$-related endocrinopathies: pathophysiology and clinical characteristics. Curr Opin Pediatr *26:493–499, 2014, Table 2, p. 495.*

In children with **Down syndrome**, antithyroid antibodies develop in approximately 30%, and subclinical or overt hypothyroidism occurs in approximately 15-20%. In girls with **Turner syndrome**, antithyroid antibodies develop in approximately 40%, and subclinical or overt hypothyroidism occurs in approximately 15-30%, rising with increasing age. In children with **type 1 diabetes mellitus**, approximately 20% develop antithyroid antibodies and 5% become hypothyroid. Additional autoimmune diseases with an increased risk of hypothyroidism include immune dysregulation–polyendocrinopathy–enteropathy–X-linked syndrome (IPEX) and IPEX-like disorders, immunoglobulin G_4–related diseases, Sjögren syndrome, multiple sclerosis, pernicious anemia, Addison disease, and ovarian failure. Although typically seen in adolescence, it occurs as early as in the 1st yr of life. **Williams syndrome** is associated with subclinical hypothyroidism; this does not appear to be autoimmune, as antithyroid antibodies are negative.

Protracted ingestion of **medications** containing iodides—for example, expectorants or nutritional supplements—can cause hypothyroidism, usually accompanied by goiter (see Chapter 567). Amiodarone, a drug used for cardiac arrhythmias and consisting of 37% iodine by weight, causes hypothyroidism in approximately 20% of treated children. It affects thyroid function directly by its high iodine content as well as by inhibition of 5′-deiodinase, which converts T_4 to T_3. Children treated with this drug should have serial measurements of T_4, T_3, and TSH.

Anticonvulsants, including phenytoin, phenobarbital, and valproate, may cause thyroid dysfunction, usually mild, subclinical hypothyroidism. Certain anticonvulsants stimulate hepatic P450 metabolism and excretion of T_4. Children with Graves disease treated with antithyroid drugs (methimazole or propylthiouracil) can develop hypothyroidism. Additional drugs that can produce hypothyroidism include lithium, tyrosine kinase inhibitors, interferon-α, stavudine, thalidomide, and aminoglutethimide.

Children who receive craniospinal irradiation, as with treatment of Hodgkin disease or other head and neck malignancies or that is administered before bone marrow transplantation, are at risk for thyroid damage. Approximately 30% of such children acquire elevated TSH levels within a year after therapy, and another 15-20% progress to hypothyroidism within 5-7 yr. Central (hypopituitary) hypothyroidism may develop in approximately 10% of children receiving craniospinal irradiation.

Radioactive iodine ablative treatment or **thyroidectomy** for Graves disease or cancer results in hypothyroidism, as can removal of ectopic thyroid tissue. Thyroid tissue in a thyroglossal duct cyst usually constitutes the only source of thyroid hormone, and excision results in hypothyroidism. Ultrasonographic examination or a radionuclide scan before surgery is indicated in these patients.

Children with **nephropathic cystinosis,** a disorder characterized by intralysosomal storage of cystine in body tissues, acquire impaired thyroid function. Hypothyroidism may be overt, but subclinical forms are more common, and periodic assessment of TSH levels is indicated. By 13 yr of age, two thirds of these patients require T_4 replacement.

Histiocytic infiltration of the thyroid in children with **Langerhans cell histiocytosis** (see Chapter 507) can result in hypothyroidism.

Children with chronic **hepatitis C infection** are at risk for subclinical hypothyroidism; this does not appear to be autoimmune, because antithyroid antibodies are negative.

Hypothyroidism can occur in children with large **hemangiomas** of the liver, because of increased type 3 deiodinase activity, which catalyzes conversion of T_4 to reverse T_3 and T_3 to diiodothyronine. Thyroid secretion is increased, but it is not sufficient to compensate for the large increase in degradation of T_4 to reverse T_3.

Some patients with congenital thyroid dysgenesis and residual thyroid function or with incomplete genetic defects in thyroid hormone synthesis do not display clinical manifestations until childhood and appear to have acquired hypothyroidism. Although these conditions are usually now detected by newborn screening programs, very mild defects can escape detection.

Any **hypothalamic** or **pituitary** disease can cause acquired central hypothyroidism (see Chapter 557). TSH deficiency may be the result of a hypothalamic-pituitary tumor (craniopharyngioma is most common in children) or a result of treatment for the tumor. Other causes include cranial radiation, head trauma, or diseases infiltrating the pituitary gland, such as Langerhans cell histiocytosis.

Clinical Manifestations

Deceleration of growth is usually the first clinical manifestation, but this sign often goes unrecognized (Figs. 565-3 and 565-4). Goiter associated with Hashimoto thyroiditis, which may be a presenting feature, typically is nontender and firm, with a rubbery consistency and a pebbly surface. Weight gain is mostly fluid retention (myxedema), not true obesity. Myxedematous changes of the skin, constipation, cold intolerance, decreased energy, and an increased need for sleep develop insidiously. Surprisingly, schoolwork and grades usually do not suffer, even in severely hypothyroid children. Additional features include bradycardia, muscle weakness or cramps, nerve entrapment, and ataxia. Osseous maturation is delayed, often strikingly, which is an indication of the duration of the hypothyroidism. Adolescents typically have delayed puberty; older adolescent girls manifest menometrorrhagia. Younger children might present with galactorrhea or pseudoprecocious puberty. Galactorrhea is a result of increased TRH stimulating prolactin secretion. The precocious puberty, characterized by breast development and vaginal bleeding in girls and macroorchidism in boys, is thought to be the result of abnormally high TSH concentrations binding to the follicle-stimulating hormone receptor with subsequent stimulation.

Some children have headaches and vision problems; they usually have enlargement of the pituitary gland, sometimes with suprasellar extension, after long-standing primary hypothyroidism. This condition, believed to be the result of thyrotroph hyperplasia, may be mistaken for a pituitary tumor (see Chapter 557). Abnormal laboratory studies include hyponatremia, macrocytic anemia, hypercholesterolemia, and elevated creatine phosphokinase. Table 565-6 lists the complications seen in severe hypothyroidism. All these changes return to normal with adequate replacement of T_4.

Diagnostic Studies

Children with suspected hypothyroidism should undergo measurement of serum free T_4 and TSH. Because the normal range for thyroid tests is slightly higher in children than adults, it is important to compare results to age-specific reference ranges. Measurement of antithyroglobulin and antiperoxidase antibodies can pinpoint autoimmune thyroiditis as the cause. In cases with a goiter resulting from autoimmune thyroid disease, an ultrasound examination typically shows diffuse enlargement with scattered hypoechogenicity. However, generally, sonography is not indicated unless there is a suspicion of a thyroid nodule on neck palpation. In such cases, ultrasound examination is the most accurate study to confirm the presence of a nodule and determine if other, smaller nodules are present. In addition, an ultrasound examination can determine the nodule dimensions, texture (solid vs cystic nature), and presence or absence of other features that might influence a decision to undertake fine-needle aspiration, such as microcalcifications, blurred margins, "taller-than-wide" shape, intranodular vascular flow, and pathologic-appearing adjacent lymph nodes (see Chapter 569.1). In children with a nodule and suppressed TSH, a radioactive iodine uptake scan is indicated to determine if this is a "hot" or hyperfunctioning nodule. A bone age x-ray at diagnosis is useful, in that the degree of delay approximates duration and severity of hypothyroidism.

Treatment and Prognosis

L-T_4 is the treatment of choice in children with hypothyroidism. The dose on a weight basis gradually decreases with age. For children age 1-3 yr, the average L-T_4 dosage is 4-6 μg/kg/day; for age 3-10 yr, 3-5 μg/kg/day; and for age 10-16 yr, 2-4 μg/kg/day. Treatment should be monitored by measuring serum free T_4 and TSH every 4-6 mo as well as 6 wk after any change in dosage. In children with central hypothyroidism, where TSH levels are not helpful in monitoring treatment, the goal should be to maintain serum free T_4 in the upper half of the normal reference range for age.

During the 1st yr of treatment, deterioration of schoolwork, poor sleeping habits, restlessness, short attention span, and behavioral

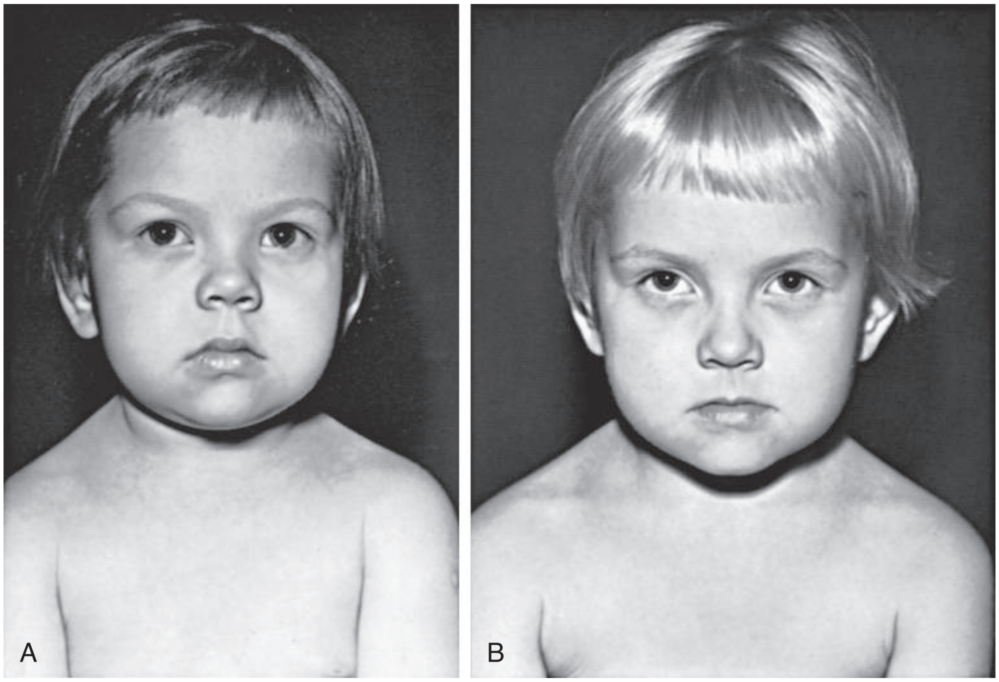

Figure 565-3 **A,** Acquired hypothyroidism in a girl 6 yr of age. She was treated with a wide variety of hematinics for refractory anemia for 3 yr. She had almost complete cessation of growth, constipation, and sluggishness for 3 yr. The height age was 3 yr; the bone age was 4 yr. She had a sallow complexion and immature facies with a poorly developed nasal bridge. Serum cholesterol, 501 mg/dL; radioiodine uptake, 7% at 24 hr; protein-bound iodine (PBI), 2.8 mg/dL. **B,** After therapy for 18 mo, note the nasal development, increased luster and decreased pigmentation of hair, and maturation of the face. The height age was 5.5 yr; the bone age was 7 yr. There was a decided improvement in her general condition. Menarche occurred at 14 yr. The ultimate height was 155 cm (61 in). She graduated from high school. The disorder was well controlled with sodium–L-thyroxine daily.

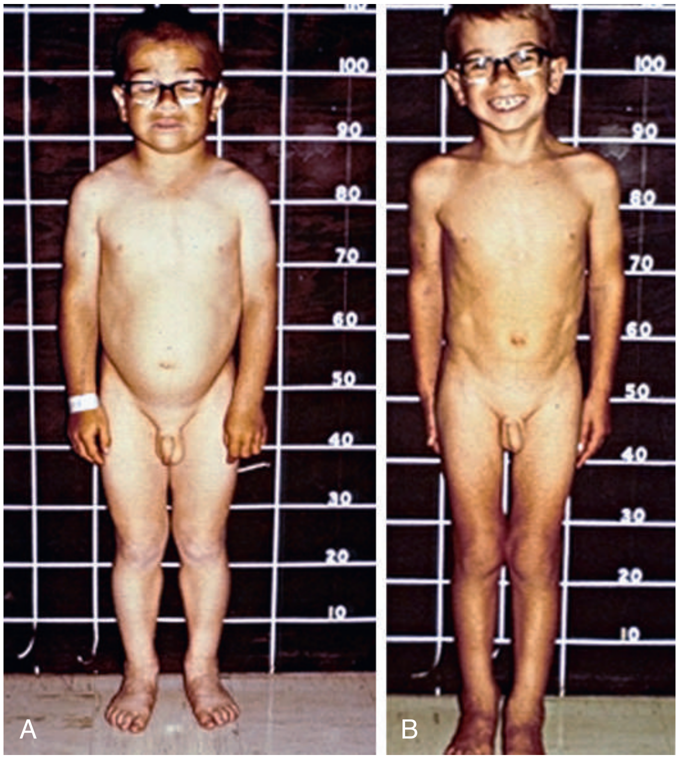

Figure 565-4 **A,** Short stature (108 cm, <3rd percentile), generalized myxedema, sleepy expression, protuberant abdomen, and coarse hair are signs of hypothyroidism in this 12 yr old boy. Body proportions are immature for his age (1.25 : 1). **B,** Same boy 4 mo after treatment. His height increased by 4 cm; note the marked change in body habitus owing to loss of generalized myxedema, improved muscle tone, and bright facial expression. *(From LaFranchi SH: Hypothyroidism,* Pediatr Clin North Am *26:33–51, 1979.)*

Table 565-6 Pathogenesis of General Complications in Management of Complicated Hypothyroidism

COMPLICATION	PATHOGENESIS
Heart failure	Impaired ventricular systolic and diastolic functions and increased peripheral vascular resistance
Ventilatory failure	Blunted hypercapnic and hypoxic ventilatory drives
Hyponatremia	Impaired renal free water excretion and syndrome of inappropriate antidiuretic hormone secretion
Ileus	Bowel hypomotility
Medication sensitivity	Reduced clearance rate and increased sensitivity to sedative, analgesic, and anesthetic agents
Hypothermia and lack of febrile response to sepsis	Decreased calorigenesis
Delirium, dementia, seizure, stupor, and coma	Decreased central nervous system thyroid hormone actions, and encephalopathy from hyponatremia and hypercapnia
Adrenal insufficiency	Associated intrinsic adrenal or pituitary disease, or reversible impairment of hypothalamic-pituitary-adrenal stress response
Coagulopathy	Acquired von Willebrand syndrome (type 1) and decreased factors VIII, VII, V, IX, and X

From Roberts CG, Landenson PW: Hypothyroidism, Lancet *363:793–803, 2004.*

problems might ensue, but these are transient; forewarning families about these manifestations enhances appropriate management. These may partially be ameliorated by starting at subreplacement T_4 doses and advancing slowly. The development of persistent headaches or vision changes should prompt an evaluation for papilledema associated with pseudotumor cerebri, a rare complication following initiation of L-T_4 treatment in older children (age 8-13 yr).

In older children, after catch-up growth is complete, the growth rate provides a good index of the adequacy of therapy. Periodic bone age x-rays are useful to monitor treatment and future growth potential. In children with long-standing hypothyroidism, catch-up growth may be incomplete (see Fig. 565-4). During the 1st 18 mo of treatment, skeletal maturation often exceeds expected linear growth, resulting in a loss of approximately 7 cm of predicted adult height.

Chapter 566

Thyroiditis

Stephen H. LaFranchi and
Stephen A. Huang

CHRONIC LYMPHOCYTIC THYROIDITIS (HASHIMOTO THYROIDITIS, AUTOIMMUNE THYROIDITIS)

Chronic lymphocytic thyroiditis is the most common cause of thyroid disease in children and adolescents and accounts for many of the enlarged thyroids formerly designated "adolescent" or "simple" goiter. It is also the most common cause of acquired hypothyroidism, with or without goiter.

One to 2% of younger school-age children and 6-8% of adolescents have positive antithyroid antibodies as evidence of autoimmune thyroid disease.

Etiology

This typical organ-specific autoimmune disease results from inheritance of susceptible genes involved in immunoregulation and environmental triggers, both as yet poorly characterized. Early in the course of the disease, there may be thyroid hyperplasia only; this is followed by infiltration of lymphocytes and plasma cells between the follicles and by atrophy of the follicles. Lymphoid follicle formation with germinal centers is almost always present; the degree of atrophy and fibrosis of the follicles varies from mild to moderate.

Intrathyroidal lymphocyte subsets differ from those in blood. Approximately 60% of infiltrating lymphoid cells are T cells, and approximately 30% express B-cell markers; the T-cell population is represented by helper ($CD4^+$) and cytotoxic ($CD8^+$) cells. The participation of cellular events in the pathogenesis is clear. Certain human leukocyte antigen (HLA) haplotypes (HLA-DR4, HLA-DR5) are associated with an increased risk of goiter and thyroiditis, and others (HLA-DR3) are associated with the atrophic variant of thyroiditis.

A variety of different thyroid antigen autoantibodies are also involved. Thyroid antiperoxidase antibodies (TPO-Abs) and antithyroglobulin antibodies (anti-Tg Abs) are demonstrable in the sera of 90% of children with chronic lymphocytic thyroiditis and in many patients with Graves disease. TPO-Abs are involved in activation of the complement cascade and in antibody-dependent, cell-mediated cytotoxicity. Anti-Tg Abs do not appear to play a role in the autoimmune destruction of the gland. Thyroid-stimulating hormone (TSH) receptor–blocking antibodies are related to the development of hypothyroidism and thyroid atrophy; they have been demonstrated in 18% of patients with severe hypothyroidism (TSH >20 mU/L) caused by autoimmune thyroiditis. Antibodies to pendrin, an apical protein on thyroid follicular cells, have been demonstrated in 80% of children with autoimmune thyroiditis. Antibodies also have been found against the sodium–iodide symporter, but their pathogenic role is unclear.

Clinical Manifestations

The disorder is 4-6 times more common in girls than in boys. It can occur during the 1st 3 yr of life, but becomes sharply more common after 6 yr of age and reaches a peak incidence during adolescence. The most common clinical manifestations are goiter and growth retardation. The goiter can appear insidiously and may be small or large. In most patients, the thyroid is diffusely enlarged, firm, and nontender. In approximately 30% of patients, the gland is asymmetric and can seem to be nodular. Most of the affected children are clinically euthyroid and asymptomatic; some may have symptoms of pressure in the neck, including difficulty swallowing and shortness of breath. Some children have clinical signs of hypothyroidism, but others who appear clinically euthyroid have laboratory evidence of hypothyroidism. A few children have manifestations suggesting hyperthyroidism, such as nervousness, irritability, increased sweating, and hyperactivity, but results of laboratory studies are not necessarily those of hyperthyroidism. Occasionally, the disorder coexists with Graves disease ("Hashitoxicosis"). Ophthalmopathy can occur in autoimmune thyroiditis in the absence of Graves disease.

The clinical course is variable. The goiter might become smaller or might disappear spontaneously, or it might persist unchanged for years while the patient remains euthyroid. Most children who are euthyroid at presentation remain euthyroid, although a percentage of patients acquire hypothyroidism gradually within months or years. In children who initially have mild or subclinical hypothyroidism (elevated serum TSH, normal free thyroxine [T_4] level), over several years approximately 40% revert to euthyroidism, 50% continue to have subclinical hypothyroidism, and approximately 10% develop overt hypothyroidism (elevated serum TSH, subnormal free T_4 level). Chronic lymphocytic thyroiditis is the cause of most cases of nongoitrous (atrophic) hypothyroidism.

Familial clusters of chronic lymphocytic thyroiditis are common; the incidence in siblings or parents of affected children may be as high as 25%. TPO-Abs and anti-Tg Abs in these families appear to be inherited in an autosomal dominant fashion, with reduced penetrance in males. The concurrence within families of patients with chronic lymphocytic thyroiditis, hypothyroidism, and Graves disease provides cogent evidence for a basic relationship among these 3 conditions.

The disorder is associated with many other autoimmune disorders. Autoimmune thyroiditis occurs in 10% of patients with type I autoimmune polyglandular syndrome (APS-1), characterized by autoimmune polyendocrinopathy, candidiasis, and ectodermal dysplasia (APECED). APS-1 consists of 2 of the triad of hypoparathyroidism, Addison disease, and mucocutaneous candidiasis (HAM syndrome). This relatively rare autosomal recessive disorder occurs in childhood and is caused by mutations in the autoimmune regulator *(AIRE)* gene on chromosome 21q22.3.

Autoimmune thyroid disease occurs in 70% of patients with APS-2. APS-2 consists of the association of autoimmune thyroiditis and Addison disease (Schmidt syndrome) or autoimmune thyroiditis with type 1 diabetes mellitus (Carpenter syndrome). It typically occurs in later childhood or early adulthood; the etiology is unknown. Autoimmune thyroiditis has been described in children with immunodysregulation polyendocrinopathy enteropathy X-linked (IPEX) syndrome, which includes early-onset diabetes and colitis. Autoimmune thyroid disease also tends to be associated with pernicious anemia, vitiligo, or alopecia. TPO-Abs are found in approximately 20% of white and 4% of black children with type 1 diabetes mellitus. Autoimmune thyroid disease has an increased incidence in children with congenital rubella.

Chronic lymphocytic thyroiditis also is associated with certain chromosomal disorders, particularly Turner syndrome and Down syndrome. In children with Down syndrome, one study reported that 28% had antithyroid antibodies (predominantly anti-TPOs), 7% had subclinical hypothyroidism, 7% had overt hypothyroidism, and 5% had

Table 566-1 Characteristics of Thyroiditis Syndromes

CHARACTERISTIC	HASHIMOTO THYROIDITIS	PAINLESS POSTPARTUM THYROIDITIS	PAINLESS SPORADIC THYROIDITIS	PAINFUL SUBACUTE THYROIDITIS	ACUTE SUPPURATIVE THYROIDITIS	RIEDEL THYROIDITIS
Sex ratio (F:M)	4-6:1	—	2:1	5:1	1:1	3-4:1
Cause	Autoimmune	Autoimmune	Autoimmune	Unknown (probably viral)	Infectious (bacterial)	Unknown
Pathologic findings	Lymphocytic infiltration, germinal centers, fibrosis	Lymphocytic infiltration	Lymphocytic infiltration	Giant cells, granulomas	Abscess formation	Dense fibrosis
Thyroid function	Usually euthyroidism; some hypothyroidism	Hyperthyroidism, hypothyroidism, or both	Hyperthyroidism, hypothyroidism, or both	Hyperthyroidism, hypothyroidism, or both	Usually euthyroidism	Usually euthyroidism
TPO antibodies	High titer, persistent	High titer, persistent	High titer, persistent	Low titer, or absent, or transient	Absent	Usually present
ESR	Normal	Normal	Normal	High	High	Normal
24 hr ^{123}I uptake	Variable	<5%	<5%	<5%	Normal	Low or normal

ESR, erythrocyte sedimentation rate; ^{123}I, iodine 123; TPO, thyroid peroxidase.

hyperthyroidism. In a study of girls with Turner syndrome, 41% had antithyroid antibodies (again, predominantly anti-TPOs), 18% had goiter, and 8% had subclinical or overt hypothyroidism. Another study of 75 girls with Turner syndrome found that autoimmune thyroid disease increased from the 1st (15%) to the 3rd (30%) decade of life. Boys with Klinefelter syndrome appear to be at risk for autoimmune thyroid disease. Table 566-1 compares the characteristics of Hashimoto thyroiditis to other thyroiditis syndromes.

Laboratory Findings

Thyroid function tests (free T_4 and TSH) are often normal, although the level of TSH may be slightly or even moderately elevated in some patients, which is termed *subclinical hypothyroidism.* That many children with chronic lymphocytic thyroiditis do not have elevated levels of TSH indicates that the goiter is caused by the lymphocytic infiltrations or by thyroid growth-stimulating immunoglobulins. Young children with chronic lymphocytic thyroiditis have serum TPO-Abs, but the anti-Tg Abs are positive in <50%. TPO-Abs and anti-Tg Abs are found equally in adolescents with chronic lymphocytic thyroiditis. When both tests are used, approximately 95% of patients with thyroid autoimmunity are detected. Levels in children and adolescents are lower than those in adults with Hashimoto thyroiditis, and repeated measurements are indicated in questionable instances because titers might increase later in the course of the disease. In adolescent females with overt hypothyroidism, measurement of TSH receptor–blocking antibodies may identify patients at future risk of having babies with transient congenital hypothyroidism.

Thyroid scans and ultrasonography usually are not needed. If they are done, thyroid scans reveal irregular and patchy distribution of the radioisotope, and in approximately 60% or more, the administration of perchlorate results in a >10% discharge of iodide from the thyroid gland. Thyroid ultrasonography shows heterogeneous echogenicity in most patients, along with an increased number of benign-appearing hyperplastic lymph nodes in the neck. The definitive diagnosis can be established by biopsy of the thyroid; this procedure is rarely clinically indicated.

Antithyroid antibodies also may be found in almost 50% of the siblings of affected patients and in a significant percentage of the mothers of children with Down syndrome or Turner syndrome without demonstrable thyroid disease.

Treatment

If there is evidence of overt hypothyroidism (elevated TSH, low T_4 or free T_4), replacement treatment with levothyroxine (at doses specific for size and age) is indicated. The goiter usually shows some decrease in size but can persist for years. In a euthyroid patient, treatment with suppressive doses of levothyroxine is unlikely to lead to a significant decrease in size of the goiter. Antibody levels fluctuate in both treated and untreated patients and persist for years. Because the disease is self-limited in some instances, the need for continued therapy requires periodic reevaluation. Untreated patients should also be checked periodically. Although there is some controversy about treating patients with subclinical hypothyroidism (elevated TSH, normal T_4 or free T_4), many clinicians prefer to treat such children until growth and puberty are complete, and then reevaluate their thyroid function.

Prominent **nodules** (i.e., >1 cm) that persist despite suppressive therapy should be examined histologically using fine-needle aspiration, because thyroid carcinoma or lymphoma has occurred in patients with Hashimoto thyroiditis.

OTHER CAUSES OF THYROIDITIS

Subacute granulomatous thyroiditis (de Quervain disease) is rare in children. It is thought to have a viral cause and remits spontaneously. The disorder becomes manifested by an upper respiratory infection with vague tenderness over the thyroid and low-grade fever, followed by severe pain in the region of the thyroid gland. Inflammation results in leakage of preformed thyroid hormone from the gland into the circulation. Serum levels of T_4 and triiodothyronine are elevated while TSH is suppressed, and mild symptoms of hyperthyroidism may be present, but radioiodine uptake is depressed. The erythrocyte sedimentation rate is increased. The course is variable but usually characterized by 4 phases: hyperthyroidism, usually followed by a euthyroid phase and then a hypothyroid phase, and remission usually occurring in several months, with recovery to euthyroidism.

Acute suppurative thyroiditis is uncommon in children; it is usually preceded by a respiratory infection with pharyngitis. The left lower lobe is affected predominantly. Abscess formation can occur; anaerobic organisms, with or without aerobes, are the typical infectious agents. The most common organism is α-hemolytic streptococci (viridans) followed by *Staphylococcus aureus* and pneumococci. Recurrent episodes or detection of a mixed bacterial flora suggests that the infection arises from a **piriform sinus fistula** or, less commonly, from a **thyroglossal duct** remnant. Exquisite tenderness of the gland, swelling, erythema, dysphagia, and limitation of head motion are characteristic findings. Fever, chills, and sore throat are not uncommon, and leukocytosis is present. Scintigrams of the thyroid often reveal decreased uptake in the affected areas, and ultrasonography might show a complex echogenic mass. Thyroid function is usually normal, but hyperthyroidism caused by escape of thyroid hormone has been encountered in a child with suppurative thyroiditis resulting from *Aspergillus.* When abscesses form, incision and drainage and administration of parenteral antibiotics are indicated. After the infection

subsides, a barium esophagram or CT scan with contrast is indicated to search for a fistulous tract; if one is found, surgical excision is indicated.

Specific conditions such as tuberculosis, sarcoidosis, mumps, and cat-scratch disease are rare causes of thyroiditis in children. **Other forms of thyroiditis** seen in adults, such as painless sporadic thyroiditis and Riedel thyroiditis, are rare in children (see Table 566-1).

Chapter 567
Goiter

Stephen A. Huang and Stephen H. LaFranchi

A goiter, or thyromegaly, is an enlargement of the thyroid gland. Persons with enlarged thyroids can have normal function of the gland **(euthyroidism),** thyroid deficiency **(hypothyroidism),** or overproduction of the hormones **(hyperthyroidism).** Goiter may be congenital or acquired, endemic or sporadic. Detection of a goiter should prompt an investigation of its cause and the assessment of thyroid function.

Goiter most often results from the increased pituitary secretion of thyroid-stimulating hormone (TSH) in response to decreased circulating levels of thyroid hormones. Activation of the TSH receptor from thyrotropin receptor–stimulating antibodies (in Graves disease), gain-of-function TSH receptor mutations, or inappropriate TSH secretion (from dominant negative thyroid hormone receptor mutations or TSH-secreting adenomas) can also cause thyromegaly. Thyroid enlargement can also result from infiltrative processes that may be inflammatory or neoplastic.

567.1 Congenital Goiter

Stephen A. Huang and Stephen H. LaFranchi

Congenital goiter is usually sporadic and can result from a fetal thyroxine (T_4) synthetic defect or from administration of antithyroid drugs or iodides during pregnancy for the treatment of maternal thyrotoxicosis. Goitrogenic drugs that cross the placenta at high doses can interfere with synthesis of thyroid hormone, resulting in goiter and hypothyroidism in the fetus. These effects are most severe when pharmacologic overtreatment with antithyroid drugs causes concomitant hypothyroidism in the mother and reduces the supply of maternal thyroid hormone available to the fetus. In women with Graves disease receiving antithyroid drugs, fetal effects can occur when the mother takes propylthiouracil at only 100-200 mg/24 hr; consequently, all infants born to women treated with antithyroid drugs in the 3rd trimester should undergo thyroid studies at birth. Even when the infant is clinically euthyroid, there may be retardation of osseous maturation, low levels of T_4, and elevated levels of TSH. Administration of thyroid hormone to affected infants may be indicated to treat clinical hypothyroidism, to hasten the disappearance of the goiter, and to prevent brain damage. Because the condition is rarely permanent, thyroid hormone may be safely discontinued after the antithyroid drug has been excreted by the neonate, usually after 1-2 wk. In addition to antithyroid medications, iodides are included in many proprietary cough preparations used to treat asthma; these preparations should be avoided during pregnancy because they have often been reported to cause congenital goiter. Amiodarone, an antiarrhythmic drug with 37% iodine content, has also caused congenital goiter with hypothyroidism.

Enlargement of the thyroid at birth may occasionally be sufficient to cause respiratory distress that interferes with nursing and can even cause death. The head may be maintained in extreme hyperextension. In pregnant women who are overtreated with antithyroid drugs, the prenatal diagnosis of even massive fetal goiter can often be corrected by withdrawal of the maternal medication, with or without intraamniotic thyroid hormone injection. When postnatal respiratory obstruction is severe, partial thyroidectomy rather than tracheostomy is indicated (Fig. 567-1).

Goiter is almost always present in the infant with neonatal Graves hyperthyroidism. Thyroid enlargement results from transplacental passage of maternal thyroid-stimulating immunoglobulin (see Chapter 568.2). These goiters usually are not large; the infant manifests clinical symptoms of hyperthyroidism. The mother often has a history of Graves disease, or the diagnosis of maternal Graves may be revealed through the evaluation of neonatal hyperthyroidism. TSH receptor–activating mutations are also a recognized cause of congenital goiter and hyperthyroidism.

When no causative factor is identifiable from the maternal or medication history, a **defect in synthesis** of thyroid hormone should be suspected. Neonatal screening programs find congenital hypothyroidism caused by such a defect in 1 in 30,000-50,000 live births. It is advisable to treat immediately with thyroid hormone and to postpone more-detailed studies for later in life. If a specific defect is suspected,

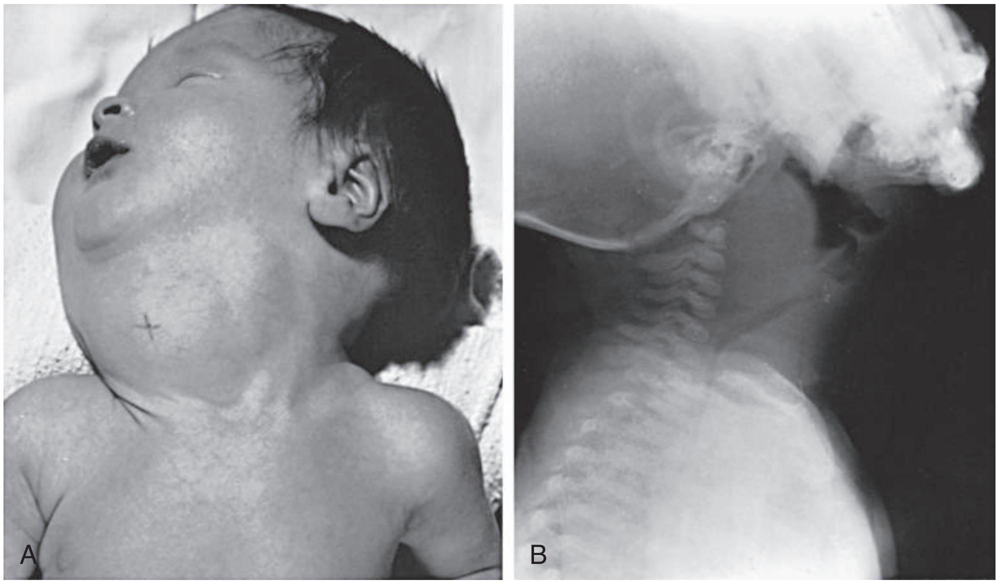

Figure 567-1 Congenital goiter in infancy. **A,** Large congenital goiter in an infant born to a mother with thyrotoxicosis who had been treated with iodides and methimazole during pregnancy. **B,** A different infant, 6 wk old, with increasing respiratory distress and cervical mass since birth. The operation revealed a large goiter that almost completely encircled the trachea. Notice the anterior deviation and posterior compression of the trachea. Partial thyroidectomy completely relieved the symptoms. It is apparent why a tracheostomy is not adequate treatment for these infants. The cause for the goiter was not found.

genetic tests to identify a mutation may be undertaken (see Chapter 565). Because these defects are often caused by recessive mutations, a precise diagnosis is helpful for genetic counseling. Monitoring subsequent pregnancies with ultrasonography can be useful in detecting fetal goiters (see Chapter 96).

Pendred syndrome, characterized by familial goiter and neurosensory deafness, is caused by a mutation in the *SLC26A4* gene, which encodes the pendrin chloride–iodide transport protein expressed in the thyroid gland and cochlea. This defect results in abnormal iodide organification in the thyroid and can cause a goiter at birth. The more common presentation is a euthyroid goiter and sensorineural hearing loss later in life.

Iodine deficiency as a cause of congenital goiter is rare in developed countries but persists in isolated endemic areas (see Chapter 567.3). More important is the recognition that severe iodine deficiency early in pregnancy can cause neurologic damage during fetal development, even in the absence of goiter. The iodine deficiency can result in combined maternal and fetal hypothyroidism, reducing the protective transfer of maternal thyroid hormones.

When the "goiter" is lobulated, asymmetric, firm, or large to an unusual degree, a teratoma within or in the vicinity of the thyroid must be considered in the differential diagnosis (see Chapter 569).

Bibliography is available at Expert Consult.

567.2 Intratracheal Goiter

Stephen A. Huang and Stephen H. LaFranchi

One of the many ectopic locations of thyroid tissue is within the trachea. The intraluminal thyroid lies beneath the tracheal mucosa and is often continuous with the normally situated extratracheal thyroid gland. The thyroid is susceptible to goitrous enlargement, which involves both the eutopic and ectopic thyroid tissue. When there is obstruction of the airway associated with a goiter, it must be ascertained whether the obstruction is extratracheal or endotracheal. If obstructive manifestations are mild, administration of sodium L-thyroxine (levothyroxine) usually causes the goiter to decrease in size. When symptoms are severe, surgical removal of the endotracheal goiter is indicated.

567.3 Endemic Goiter and Cretinism

Stephen A. Huang and Stephen H. LaFranchi

ETIOLOGY

The association between dietary deficiency of iodine and the prevalence of goiter or cretinism is well established. A moderate deficiency of iodine can be overcome by increased efficiency in the synthesis of thyroid hormone. Iodine liberated in the tissues is returned rapidly to the gland, which resynthesizes triiodothyronine (T_3) preferentially at a higher rate than normal. This increased activity is achieved by compensatory hypertrophy and hyperplasia (goiter), which satisfy the demands of the tissues for thyroid hormone. In geographic areas where deficiency of iodine is severe, decompensation and hypothyroidism can result. Recent estimates from the World Health Organization indicate that nearly 2 billion individuals currently have insufficient iodine intake, including one third of the world's school-age children. Thus, despite great progress in the global effort to reduce iodine deficiency, it remains the leading cause of preventable intellectual disability worldwide.

Seawater is rich in iodine; the iodine content of fish and shellfish is also high. As a result, endemic goiter is rare in populations living along the coast. Iodine is deficient in the water and native foods in the Pacific West and the Great Lakes areas of the United States. Deficiency of dietary iodine is even greater in certain Alpine valleys, the Himalayas, the Andes, the Congo, and the highlands of Papua New Guinea. In areas such as the United States, where iodine is provided in foods from other areas and in iodized salt, endemic goiter has disappeared. Iodized salt in the United States contains potassium iodide (100 µg/g), which provides excellent prophylaxis. Further iodine intake in the United States is contributed by iodates used in baking, iodine-containing coloring agents, and iodine-containing disinfectants used in the dairy industry. The recommended daily allowance of iodine is as follows:

- Children younger than 2 yr: ≥100 µg/day
- School-age children: 100-299 µg/day
- Pregnant women: ≥150 µg/day
- Lactating women: ≥100 µg/day

While the overall dietary iodine intake in the United States is considered adequate, the most recent NHANES (National Health and Nutrition Examination Survey) from 2007-2010 reports that the median urinary iodine concentration among pregnant U.S. women has dropped to <150 µg/L. This indicates mild iodine deficiency and highlights the risk of iodine deficiency reemergence in industrialized countries as salt intake decreases. These risks can be mitigated by the continued monitoring of iodine status, the adjustment of salt iodization levels, and the targeted supplementation of vulnerable subpopulations (promotion of iodine-containing prenatal vitamins).

CLINICAL MANIFESTATIONS

If the deficiency of iodine is mild, thyroid enlargement does not become noticeable except when there is increased demand for the hormone during periods of rapid growth, as in adolescence and during pregnancy. In regions of moderate iodine deficiency, goiter observed in school children can disappear with maturity and reappear during pregnancy or lactation. Iodine-deficient goiters are more common in girls than in boys. In areas where iodine deficiency is severe, as in the hyperendemic highlands of Papua New Guinea, nearly half the population has large goiters, and endemic cretinism is common (Fig. 567-2).

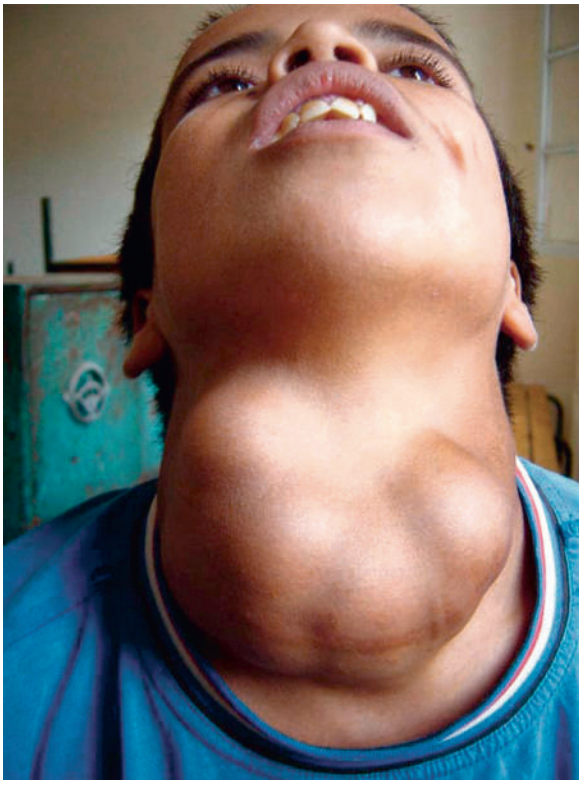

Figure 567-2 A 14 yr old boy with a large nodular goiter was seen in 2004, in an area of severe iodine-deficiency disorders in northern Morocco. He had tracheal and esophageal compression and hoarseness, probably as a result of damage to the recurrent laryngeal nerves. *(From Zimmernamm MB, Jooste PL, Pandav CS: Iodine-deficiency disorders,* Lancet *372:1251–1262, 2008, Fig 2.)*

Serum T_4 levels are often low in persons with endemic goiter, although clinical hypothyroidism is rare. This is true in New Guinea, the Congo, the Himalayas, and South America. Despite low serum T_4 levels, serum TSH concentrations are often normal or only moderately increased. In such patients, circulating levels of T_3 are elevated. Moreover, T_3 levels are also elevated in patients with normal T_4 levels, indicating a preferential secretion of T_3 by the thyroid in this disease and an adaptive increase in peripheral T_4 to T_3 conversion.

Endemic cretinism is the most serious consequence of iodine deficiency; it occurs only in geographic association with endemic goiter. The term *endemic cretinism* includes 2 different but overlapping syndromes: a **neurologic type** and a **myxedematous type.** The incidence of the 2 types varies among different populations. In Papua New Guinea, the neurologic type occurs almost exclusively, whereas in the Congo, the myxedematous type predominates. Both types are found in all endemic areas, and some persons have intermediate or mixed features.

The **neurologic syndrome** is characterized by intellectual disability, deaf-mutism, disturbances in standing and gait, and pyramidal signs such as clonus of the foot, the Babinski sign, and patellar hyperreflexia. Affected persons are goitrous but euthyroid, have normal pubertal development and adult stature, and have little or no impaired thyroid function. Persons with the **myxedematous syndrome** also are intellectually challenged and deaf and have neurologic symptoms, but in contrast to the neurologic type, they have delayed growth and sexual development, myxedema, and absence of goiter. Serum T_4 levels are low and TSH levels are markedly elevated. Delayed skeletal maturation may extend into the 3rd decade or later. Ultrasonographic examination shows thyroid atrophy.

PATHOGENESIS

The pathogenesis of the **neurologic syndrome** is attributed to iodine deficiency and hypothyroxinemia during pregnancy, leading to fetal and postnatal hypothyroidism. Although some investigators have attributed brain damage to a direct effect of elemental iodine deficiency in the fetus, most believe the neurologic symptoms are caused by combined fetal and maternal hypothyroxinemia. There is evidence for the presence of thyroid hormone receptors in the fetal brain as early as 7 wk of gestation. Although the normal fetal thyroid gland does not begin to produce significant amounts of thyroid hormone until midgestation, there is measurable T_4 in the coelomic fluid as early as 6 wk, almost certainly of maternal origin. These lines of evidence support a role for maternal thyroid hormone in fetal brain development in the 1st trimester. In addition, there is evidence of transplacental passage of maternal thyroid hormone into the fetus, which normally might ameliorate the effects of fetal hypothyroidism on the developing nervous system in the second half of pregnancy. Thus, iodine deficiency in the mother affects fetal brain development both in the 1st trimester and throughout pregnancy. Intake of iodine after birth is often sufficient for normal or only minimally impaired thyroid function.

The pathogenesis of the **myxedematous syndrome** leading to thyroid atrophy is more bewildering. Searches for additional environmental factors that might provoke continuing postnatal hypothyroidism have led to incrimination of selenium deficiency, goitrogenic foods, thiocyanates, and *Yersinia* (Table 567-1). Studies from western China suggest that thyroid autoimmunity might play a role. Children with myxedematous cretinism with thyroid atrophy, but not children with euthyroid cretinism, were found to have thyroid growth-blocking immunoglobulins of the kind found in infants with sporadic congenital hypothyroidism. Others are skeptical about any role of thyroid growth-blocking immunoglobulins to explain these findings.

Table 567-1 Goitrogens and Their Mechanism

GOITROGEN	MECHANISM
FOODS	
Cassava, lima beans, linseed, sorghum, sweet potato	Contain cyanogenic glucosides that are metabolized to thiocyanates that compete with iodine for uptake by the thyroid
Cruciferous vegetables such as cabbage, kale, cauliflower, broccoli, turnips, rapeseed	Contain glucosinolates; metabolites compete with iodine for uptake by the thyroid
Soy, millet	Flavonoids impair thyroid peroxidase activity
INDUSTRIAL POLLUTANTS	
Perchlorate	Competitive inhibitor of the sodium–iodine symporter, decreasing iodine transport into the thyroid
Others (e.g., disulfides from coal processes)	Reduce thyroidal iodine uptake
Smoking	An important goitrogen; smoking during breastfeeding is associated with reduced iodine concentrations in breast milk; high serum concentration of thiocyanate from smoking might compete with iodine for active transport into the secretory epithelium of the lactating breast
NUTRIENTS	
Selenium deficiency	Accumulated peroxides can damage the thyroid, and deiodinase deficiency impairs thyroid hormone activation
Iron deficiency	Reduces heme-dependent thyroperoxidase activity in the thyroid and might blunt the efficacy of iodine prophylaxis
Vitamin A deficiency	Increases TSH stimulation and goiter through decreased vitamin A–mediated suppression of the pituitary TSH-β gene

TSH, thyroid-stimulating hormone.

From Zimmernamm MB, Jooste PL, Pandav CS: Iodine-deficiency disorders, Lancet 372:1251–1262, 2008, Table 1.

TREATMENT

In many developing countries, administration of a single intramuscular injection of iodinated poppy seed oil to women prevents iodine deficiency during future pregnancies for approximately 5 yr. This form of therapy given to children younger than 4 yr of age with myxedematous cretinism results in a euthyroid state in 5 mo. Older children respond poorly and adults not at all to iodized oil injections, indicating an inability of the thyroid gland to synthesize hormone; these patients require treatment with T_4. Through the efforts of the World Health Organization and its program of universal salt iodization, the number of households worldwide with access to adequately iodized salt has increased from <10% in 1990 to 70% in 2012. In the Xinjiang province of China, where the usual methods of iodine supplementation had failed, iodination of irrigation water has increased iodine levels in soil, animals, and human beings. In other countries, iodinated salt in school meal programs gives children the dietary iodine they need. Still, political, economic, and practical obstacles have limited penetration of iodized food into regular diets around the world.

Bibliography is available at Expert Consult.

567.4 Acquired Goiter

Stephen A. Huang and Stephen H. LaFranchi

Most acquired goiters are sporadic and develop from a variety of causes; patients are usually euthyroid but may be hypothyroid or hyperthyroid. The most common cause of acquired goiter is

lymphocytic thyroiditis (see Chapter 566). Rarer causes in children include painless sporadic thyroiditis and subacute painful thyroiditis (de Quervain disease; see Chapter 566). Other causes include excess iodide ingestion and certain drugs, including amiodarone and lithium. Intrinsic biochemical defects in the synthesis of thyroid hormone are almost always associated with goiter; thyromegaly from milder defects occurs later in childhood. The occurrence of the disorder in siblings, onset in early life, and possible association with hypothyroidism (goitrous hypothyroidism) are important clues to the diagnosis.

IODIDE GOITER

A small percentage of patients treated with iodide preparations for prolonged periods acquire goiters. Iodides are commonly included for their expectorant effect in cough medicines and in proprietary mixtures for asthma. Goiters resulting from iodide administration are firm and diffusely enlarged, and in some instances hypothyroidism develops. In normal persons, acute administration of large doses of iodide inhibits the organification of iodine and the synthesis of thyroid hormone (Wolff-Chaikoff effect). This effect is short-lived and does not lead to permanent hypothyroidism. When iodide administration continues, an autoregulatory mechanism in normal persons limits iodide trapping and permits the level of iodide in the thyroid to decrease and organification to proceed normally. In patients with iodide-induced goiter, this escape does not occur, because of an underlying abnormality of biosynthesis of thyroid hormone. The persons most susceptible to the development of iodide goiter are those with lymphocytic thyroiditis or with a subclinical inborn error in thyroid hormone synthesis and those who have had a partial thyroidectomy.

Lithium carbonate, which is used to treat bipolar disorder, also causes goiters and mild hypothyroidism. Lithium decreases T_4 and T_3 synthesis and release; the mechanism producing the goiter or hypothyroidism is similar to that described for iodide goiter. Lithium and iodide also act synergistically to produce goiter; their combined use should be avoided.

Amiodarone, a drug used to treat cardiac arrhythmias, can cause thyroid dysfunction with goiter because it is rich in iodine. It is also a potent inhibitor of 5′-deiodinase, preventing conversion of T_4 to T_3. It can cause hypothyroidism, particularly in patients with underlying autoimmune disease. In other patients, it can cause thyrotoxicosis through either transient thyroiditis or the Jod-Basedow effect.

SIMPLE GOITER (COLLOID GOITER)

A few children with euthyroid goiters have simple goiters, a condition of unknown cause not associated with hypothyroidism or hyperthyroidism and not caused by inflammation or neoplasia. The condition predominates in girls and has a peak incidence before and during the pubertal years. Histologic examination of the thyroid either is normal or reveals variable follicular size, dense colloid, and flattened epithelium. The goiter may be small or large. It is firm in half the patients and occasionally is asymmetric or nodular. Levels of TSH are normal or low, scintiscans are normal, and thyroid antibodies are absent. Differentiation from lymphocytic thyroiditis might not be possible without a biopsy, but biopsy is usually not indicated. Therapy with thyroid hormone can help prevent progression to a large multinodular goiter, although it is difficult to separate any treatment effects from the natural history, which is for the goiter to decrease in size. Patients should be reevaluated periodically, because some have antibody-negative lymphocytic thyroiditis and therefore are at risk for changes in thyroid function (see Chapter 566).

MULTINODULAR GOITER

Rarely, a firm goiter with a lobulated surface and single or multiple palpable nodules is encountered. Areas of cystic change, hemorrhage, and fibrosis may be present. The incidence of this condition has decreased markedly with the use of iodine-enriched salt. A mild goitrogenic stimulus, acting over a long time, is thought to be the cause. Ultrasonographic examination can reveal multiple nodules that are nonfunctioning on scintiscans. Thyroid studies are usually normal. Some children with chronic lymphocytic thyroiditis develop multinodular goiter; TSH may be elevated, and thyroid antibodies may be present.

Children can develop toxic multinodular goiter, characterized by a suppressed TSH and hyperthyroidism. The condition occurs in children with **McCune-Albright syndrome** (usually resulting in hyperthyroidism), with **TSH receptor–activating mutations,** and it has been described in 3 children (including 2 siblings) with digital anomalies and cystic kidney disease. If hypofunctioning nodules within a multinodular goiter grow to significant size (≥1 cm), fine-needle aspiration should be considered to rule out malignancy (see Chapter 569).

TOXIC GOITER (HYPERTHYROIDISM)

See Chapter 568.

Chapter 568

Hyperthyroidism

Stephen A. Huang and Stephen H. LaFranchi

Hyperthyroidism results from excessive secretion of thyroid hormone; during childhood, with few exceptions, it is caused by Graves disease (Table 568-1). **Graves disease** is an autoimmune disorder; production of thyroid-stimulating immunoglobulin that binds to and activates the G-protein–coupled **thyroid-stimulating hormone (TSH) receptor** results in diffuse toxic goiter. Other causes of hyperthyroidism include gain-of-function germline mutations in the **TSH receptor**, which are found in both familial (autosomal dominant) and sporadic cases of non–autoimmune hyperthyroidism. These patients, whose disease can appear in the neonatal period or in later childhood, have thyroid hyperplasia with goiter and suppressed levels of TSH. Different activating mutations have been identified in some cases of thyroid adenomas. Hyperthyroidism occurs in some patients with **McCune-Albright syndrome** as a result of an activating mutation of the α subunit of the G-protein; these patients tend to have a multinodular goiter. Other rare causes of thyrotoxicosis that have been observed in children include painless sporadic thyroiditis, subacute painful thyroiditis, acute suppurative thyroiditis, thyrotoxicosis factitia, TSH-secreting adenomas, and hyperfunctioning thyroid carcinoma.

Suppression of plasma TSH indicates that the hyperthyroidism is not pituitary in origin. Hyperthyroidism caused by inappropriate thyrotropin secretion is rare and, in most cases, is caused by dominant negative thyroid hormone receptor mutations and pituitary resistance to thyroid hormone. TSH-secreting pituitary tumors are extremely rare in the pediatric population. In infants born to mothers with Graves disease, hyperthyroidism is almost always a transitory phenomenon; classic Graves disease during the neonatal period is rare. Choriocarcinoma, hydatidiform mole, and struma ovarii have caused hyperthyroidism in adults but have not been recognized as causes in children.

Studies have examined the health and quality of life of individuals with subclinical hyperthyroidism (i.e., with TSH <0.1 mU/L, but normal serum thyroxine [T_4] and triiodothyronine [T_3] concentrations) or who are euthyroid on antithyroid medication. These studies indicate that subclinical hyperthyroidism carries a risk of late-life atrial fibrillation, but no similar risks have been identified in the general pediatric population. There appears to be no difference in long-term quality of life among hyperthyroid patients treated with antithyroid medication, radioiodine ablation, or surgery. Quality of life was diminished relative to control persons in all 3 cases (see Chapter 568.1).

Table 568-1 Causes of Hyperthyroidism

CAUSES OF HYPERTHYROIDISM	PATHOPHYSIOLOGIC FEATURES	INCIDENCE
CIRCULATING THYROID STIMULATORS		
Graves disease	Thyroid-stimulating immunoglobulins	Common
Neonatal Graves disease	Thyroid-stimulating immunoglobulins	Rare
Thyrotropin-secreting tumor	Pituitary adenoma	Very rare
Choriocarcinoma	Human chorionic gonadotropin secretion stimulating the thyroid-stimulating hormone receptor	Rare
THYROIDAL AUTONOMY		
Toxic multinodular goiter	Activating mutations in thyrotropin receptor or G-protein	Common
Toxic solitary adenoma	Activating mutations in thyrotropin receptor or G-protein	Common
Congenital hyperthyroidism	Activating mutations in thyrotropin receptor	Very rare
Iodine-induced hyperthyroidism (Jod-Basedow phenomenon)	Unknown; excess iodine results in unregulated thyroid hormone production	Uncommon in United States and other iodine-sufficient areas
DESTRUCTION OF THYROID FOLLICLES (THYROIDITIS)		
Subacute painful thyroiditis	Probable viral infection	Uncommon
Painless sporadic thyroiditis (or postpartum thyroiditis)	Autoimmune	Common
Amiodarone-induced thyroiditis	Direct toxic drug effects	Uncommon
Acute (infectious) thyroiditis	Thyroid infection (e.g., bacterial, fungal) and release of preformed hormone	Uncommon
EXOGENOUS THYROID HORMONE		
Iatrogenic	Overtreatment with thyroid hormone	Common
Factitious	Excess ingestion of thyroid hormone	Rare
Hamburger thyrotoxicosis	Thyroid gland included in ground beef	Probably rare
ECTOPIC THYROID TISSUE		
Struma ovarii	Ovarian teratoma containing thyroid tissue	Rare
Metastatic follicular thyroid cancer	Large tumor mass capable of secreting thyroid hormone autonomously	Rare
Pituitary resistance to thyroid hormone	Mutated thyroid hormone receptor-β	Rare

568.1 Graves Disease

Stephen A. Huang and Stephen H. LaFranchi

EPIDEMIOLOGY

Graves disease occurs in approximately 0.02% of children (1 : 5,000). It has a peak incidence in the 11-15 yr old age group; there is a 5 : 1 female : male ratio. Most children with Graves disease have a positive family history of some form of autoimmune thyroid disease. In Japan, familial Graves disease, defined as Graves disease in a 1st-degree relative, occurs in 2-3% of cases.

ETIOLOGY

Enlargement of the thymus, splenomegaly, lymphadenopathy, infiltration of the thyroid gland and retroorbital tissues with lymphocytes and plasma cells, and peripheral lymphocytosis are well-established findings in Graves disease. In the thyroid gland, T-helper cells ($CD4^+$) predominate in dense lymphoid aggregates; in areas of lower cell density, cytotoxic T cells ($CD8^+$) predominate. The percentage of activated B lymphocytes infiltrating the thyroid is higher than in peripheral blood. A postulated failure of T-suppressor cells allows expression of T-helper cells, sensitized to the TSH antigen, which interact with B cells. These cells differentiate into plasma cells, which produce thyrotropin receptor–stimulating antibody (TRSAb). TRSAb binds to the receptor for TSH and stimulates cyclic adenosine monophosphate, resulting in thyroid hyperplasia and unregulated overproduction of thyroid hormone. In addition to TRSAb, thyrotropin receptor–blocking antibody (TRBAb), which binds but does not activate the TSH receptor, may also be produced, and the clinical course of the disease usually correlates with the ratio between the 2 antibodies.

The ophthalmopathy occurring in Graves disease appears to be caused by antibodies against antigens shared by the thyroid and eye muscle. TSH receptors have been identified in retroorbital adipocytes and might represent a target for antibodies. The antibodies that bind to the extraocular muscles and orbital fibroblasts stimulate the synthesis of glycosaminoglycans by orbital fibroblasts and produce cytotoxic effects on muscle cells.

In whites, Graves disease is associated with human leukocyte antigen (HLA)-B8 and HLA-DR3; the latter carries a 7-fold relative risk for Graves disease. Graves disease is also associated with other HLA-D3–related disorders, such as Addison disease, type 1 diabetes mellitus, myasthenia gravis, and celiac disease. Systemic lupus erythematosus, rheumatoid arthritis, vitiligo, idiopathic thrombocytopenic purpura, and pernicious anemia have been described in children with Graves disease. In family clusters, the conditions associated most commonly with Graves disease are autoimmune lymphocytic thyroiditis and hypothyroidism. In Japanese children, Graves disease is associated with different HLA haplotypes: HLA-DRB1*0405 and HLA-DQB1*0401. In the Chinese population, the RNASET2-FGFR1OP-CCR6 region at 6q27 and an intergenic region at 4p14 are important susceptibility loci.

CLINICAL MANIFESTATIONS

Approximately 5% of all patients with hyperthyroidism are younger than 15 yr of age; the peak incidence in these children occurs during adolescence. Although rare, Graves disease has begun between 6 wk and 2 yr of age in children born to mothers without a history of hyperthyroidism. The incidence is approximately 5 times higher in girls than in boys.

The clinical course in children is highly variable but usually is not so fulminant as in many adults (Table 568-2). Symptoms develop gradually; the usual interval between onset and diagnosis is 6-12 mo and may be longer in prepubertal children compared with adolescents. The earliest signs in children may be emotional disturbances accompanied by motor hyperactivity. The children become irritable and excitable, and they cry easily because of emotional lability. They are restless sleepers and tend to kick their covers off. Their schoolwork suffers as a result of a short attention span and poor sleep. Tremor of the fingers can be

Table 568-2	Major Symptoms and Signs of Hyperthyroidism and of Graves Disease and Conditions Associated with Graves Disease

MANIFESTATIONS OF HYPERTHYROIDISM
Symptoms
Hyperactivity, irritability, altered mood, insomnia, anxiety, poor concentration
Heat intolerance, increased sweating
Palpitations
Fatigue, weakness
Dyspnea
Weight loss with increased appetite (weight gain in 10% of patients)
Pruritus
Increased stool frequency
Thirst and polyuria
Oligomenorrhea or amenorrhea
Signs
Sinus tachycardia, atrial fibrillation (rare in children), supraventricular tachycardia
Fine tremor, hyperkinesis, hyperreflexia
Warm, moist skin
Palmar erythema, onycholysis
Hair loss or thinning
Osteoporosis
Muscle weakness and wasting
High-output heart failure
Chorea
Periodic (hypokalemic) paralysis (primarily in Asian men)
Psychosis (rare)

MANIFESTATIONS OF GRAVES DISEASE
Diffuse goiter
Ophthalmopathy
A feeling of grittiness and discomfort in the eye
Retrobulbar pressure or pain
Eyelid lag or retraction
Periorbital edema, chemosis, scleral or conjunctival injection
Exophthalmos (proptosis)
Extraocular muscle dysfunction
Exposure keratitis
Optic neuropathy
Localized dermopathy (rare in children)
Lymphoid hyperplasia
Thyroid acropachy (rare in children)

CONDITIONS ASSOCIATED WITH GRAVES DISEASE
Type 1 diabetes mellitus
Addison disease
Vitiligo
Pernicious anemia
Alopecia areata
Myasthenia gravis
Celiac disease

Adapted from Weetman AP: Graves disease, N Engl J Med *343:1236–1248, 2000.*

Figure 568-1 A 15 yr old girl with classic Graves disease. Clinical features include a goiter and exophthalmos. She was treated with antithyroid drugs, to which she had a good response.

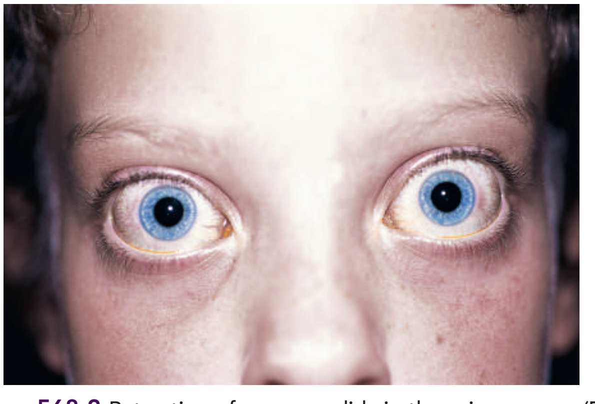

Figure 568-2 Retraction of upper eyelids in the primary gaze (Dalrymple sign). *(From Kanski JJ:* Systemic diseases and the eye: signs and differential diagnosis, *London, 2001, Mosby.)*

noticed if the arm is extended. There may be a voracious appetite combined with loss of or no increase in weight. Recent height measurements might show acceleration in growth velocity.

The size of the thyroid is variable. It may be so minimally enlarged that it initially escapes detection, but with careful examination, a diffuse goiter, soft with a smooth surface, is found in almost all patients. Exophthalmos is noticeable in most patients but is usually mild. Lagging of the upper eyelid as the eye looks downward, impairment of convergence, and retraction of the upper eyelid and infrequent blinking may be present (Figs. 568-1 and 568-2). Ocular manifestations can produce pain, lid erythema, chemosis, decreased extraocular muscle function, and decreased visual acuity (corneal or optic nerve involvement). The skin is smooth and flushed, with excessive sweating. Muscular weakness is uncommon but may be severe enough to result in clumsiness. Tachycardia, palpitations, dyspnea, and cardiac enlargement and insufficiency cause discomfort but rarely endanger the patient's life. Atrial fibrillation is a rare complication. Mitral regurgitation, probably resulting from papillary muscle dysfunction, is the cause of the apical systolic murmur present in some patients. The systolic blood pressure and the pulse pressure are increased. Reflexes are brisk, especially the return phase of the Achilles reflex. Many of the findings in Graves disease result from hyperactivity of the sympathetic nervous system.

Thyroid crisis, or thyroid storm, is a form of hyperthyroidism manifested by a severe biochemical derangement, acute onset, hyperthermia, tachycardia, heart failure, and restlessness. There may be rapid progression to delirium, coma, and death. Precipitating events include trauma, infection, radioactive iodine treatment, or surgery. **Apathetic**

(or **masked**) **hyperthyroidism** is another variety of hyperthyroidism characterized by extreme listlessness, apathy, and cachexia. A combination of both forms can occur. These symptom complexes are rare in children.

LABORATORY FINDINGS

Levels of TSH are suppressed to below the lower range of normal. Serum levels of T_4, T_3, free T_4, and free T_3 are typically elevated. In some patients, levels of T_3 may be more elevated than those of T_4. Antithyroid antibodies, including thyroid peroxidase antibodies, are often present. Most patients with newly diagnosed Graves disease have measurable TRSAb; the 2 methods to measure TRSAb are thyroid-stimulating immunoglobulin or thyrotropin-binding inhibitory immunoglobulin. Measurement of thyroid-stimulating immunoglobulin or thyrotropin-binding inhibitory immunoglobulin is useful in confirming the diagnosis of Graves disease. Children who experience an acceleration of growth might also have advanced skeletal maturation. Bone density may be reduced at diagnosis but returns to normal with treatment.

DIFFERENTIAL DIAGNOSIS

Diagnosis is rarely difficult once hyperthyroidism is considered. Elevated levels of T_4 or free T_4 and T_3 in association with suppressed levels of TSH are usually diagnostic (see Table 568-1). The combination of diffuse goiter and prolonged hyperthyroidism is nearly always caused by Graves disease, and the presence of characteristic eye or skin changes is diagnostic. Documentation of elevated TRSAb can confirm the diagnosis.

Other causes of hyperthyroidism are uncommon. In rare cases where clinical assessment cannot distinguish Graves hyperthyroidism from painless sporadic thyroiditis, ^{123}I radioiodine uptake can be measured and used to determine the appropriateness of antithyroid medication. If a discrete thyroid nodule is palpated, a ^{123}I scan should be performed to assess the possibility of a hyperfunctioning nodule(s). Some children with toxic multinodular goiter may have either a TSH receptor–activating mutation or McCune-Albright syndrome. If precocious puberty, polyostotic fibrous dysplasia, or café-au-lait pigmentation is present, the autonomous thyroid disorder of McCune-Albright syndrome is likely. Patients with generalized thyroid hormone resistance have elevated levels of free T_4 and free T_3, but levels of TSH are inappropriately elevated or normal. They must be differentiated from patients with TSH-secreting pituitary tumors who have elevated serum levels of the TSH α subunit. Most other causes of hyperthyroxinemia are uncommon but can result in erroneous diagnosis. Patients with elevated T_4-binding globulin levels or familial dysalbuminemic hyperthyroxinemia have normal levels of free T_4 and TSH. Rare patients with mutations in *SLC16A2* (encoding the MCT8 thyroid hormone transporter) or *THRA* (encoding thyroid hormone receptor α) can present with high serum T_3 and inappropriately normal or high TSH but low serum T_4 concentrations.

When hyperthyroxinemia is caused by **exogenous thyroid hormone (thyrotoxicosis factitia),** levels of free T_4 and TSH are the same as those seen in Graves disease but, in contrast to Graves hyperthyroidism, serum thyroglobulin is very low, thyroid size is small, and ^{123}I radioiodine uptake is suppressed.

TREATMENT

Most pediatric endocrinologists recommend initial medical therapy using antithyroid drugs rather than radioiodine or subtotal thyroidectomy, although radioiodine is gaining acceptance as initial treatment in children older than 10 yr of age. All therapeutic options have advantages and disadvantages (Table 568-3). The 2 antithyroid drugs used historically are propylthiouracil and methimazole (Tapazole). Both compounds inhibit incorporation of trapped inorganic iodide into organic compounds. However, there are important differences between the drugs. Methimazole is at least 10 times more potent than propylthiouracil on a weight basis and has a much longer serum half-life (6-8 hr vs 0.5 hr); propylthiouracil generally is administered 3 times daily, but methimazole can be given once daily. Unlike methimazole, propylthiouracil is heavily protein bound and has a lesser ability to cross the placenta and to pass into breast milk; theoretically, therefore, propylthiouracil is the preferred drug during pregnancy and for nursing mothers. Because of reports of **severe liver disease** in patients treated with **propylthiouracil,** with some patients requiring liver transplant or potentially suffering a fatal outcome, the consensus is to **use only methimazole** to treat children with Graves disease.

Adverse reactions occur with antithyroid drugs; most are mild, but some are life-threatening. Minor adverse effects occur in approximately 10-20%, and more-severe adverse effects occur in 2-5% of children. Reactions are unpredictable and can occur after therapy of any duration. Transient granulocytopenia (<2,000/mm^3) is common; it is asymptomatic and is not a harbinger of agranulocytosis, and it usually is not a reason to discontinue treatment. Transient urticarial rashes are common. They may be managed by a short period off therapy, and then restarting the antithyroid drug. The most severe reactions are hypersensitive and include agranulocytosis (0.1-0.5%), hepatitis (0.2-1.0%), a lupus-like polyarthritis syndrome, glomerulonephritis, and an antineutrophilic cytoplasmic antibody–positive vasculitis involving the skin and other organs. **Severe liver disease**, including liver failure requiring transplantation, have been reported **exclusively**

Table 568-3 Treatments for Hyperthyroidism Caused by Graves Disease

TREATMENT	ADVANTAGE	DISADVANTAGE	COMMENT
Antithyroid drugs	Noninvasive Less initial cost Low risk of permanent hypothyroidism Possible remission	Cure rate 30-80% (average: 40-50%) Adverse drug reactions Drug compliance required	First-line treatment in children and adolescents and in pregnancy Initial treatment in severe cases or preoperative preparation
Radioactive iodine (^{131}I)	Cure of hyperthyroidism Most cost-effective	Permanent hypothyroidism is almost inevitable Might worsen ophthalmopathy Pregnancy must be deferred for 6-12 mo, mother cannot breastfeed; small potential risk of exacerbation of hyperthyroidism	No evidence for infertility, birth defects, cancer when currently recommended doses are applied
Surgery	Rapid, effective treatment especially in patients with large goiter	Most invasive therapy Potential complications (recurrent laryngeal nerve damage, hypoparathyroidism) Most costly therapy Permanent hypothyroidism; pain; scarring	Potential use in pregnancy if major side effect from antithyroid drugs Useful when coexisting suspicious nodule is present or thyromegaly is massive Option for patients who refuse radioiodine

From Cooper DS: Hyperthyroidism, Lancet *362:459–468, 2003.*

with propylthiouracil. The most common liver disease associated with methimazole is cholestatic jaundice, reversible when the drug is discontinued. Patients with severe adverse effects should be treated with radioiodine or thyroidectomy. In rare instances where hyperthyroidism is severe and methimazole cannot be used, a short course of propylthiouracil may be offered to restore euthyroidism prior to definitive therapy. Cases of congenital skin defects (aplasia cutis) have been seen in infants exposed in fetal life to methimazole, but this association does not appear to be a strong one.

The initial dosage of methimazole is 0.25-1.0 mg/kg/24 hr given once or twice daily. Smaller initial dosages should be used in early childhood. Careful surveillance is required after treatment is initiated. Rising serum levels of TSH to greater than normal indicates overtreatment and leads to increased size of the goiter. Clinical response becomes apparent in 3-6 wk, and adequate control is evident in 3-4 mo. The dose is decreased to the minimal level required to maintain a euthyroid state.

Most studies report a remission rate of approximately 25% after 2 yr of antithyroid drug treatment in children. Some studies find that longer treatment is associated with higher remission rates, with 1 study reporting a 50% remission rate after 4.5 yr of drug treatment. If a relapse occurs, it usually appears within 3 mo and almost always within 6 mo after therapy has been discontinued. Therapy may be resumed in case of relapse. Patients older than 13 yr of age, boys, those with a higher body mass index, and those with small goiters and modestly elevated T_3 levels appear to have earlier remissions.

A β-adrenergic blocking agent such as propranolol (0.5-2.0 mg/kg/24 hr orally, divided 3 times daily) or atenolol (1-2 mg/kg orally given once daily) is a useful supplement to antithyroid drugs in the management of severely toxic patients. Table 568-4 lists additional therapies for **thyroid storm.** Thyroid hormones potentiate the actions of catecholamines, including tachycardia, tremor, excessive sweating, lid lag, and stare. These symptoms abate with the use of propranolol, which does not, however, alter thyroid function or exophthalmos.

Radioiodine treatment or surgery is indicated when adequate cooperation for medical management is not possible, when an adequate trial of medical management has failed to result in permanent remission, or when severe side effects preclude further use of antithyroid drugs. Either of these treatments may also be preferred by the patient or parent.

Table 568-4 Management of Thyroid Storm in Adolescents

GOAL	TREATMENT
Inhibition of thyroid hormone formation and secretion	Propylthiouracil, 400 mg every 8 hr PO or by nasogastric tube Saturated solution of potassium iodide, 3 drops every 8 hr
Sympathetic blockade	Propranolol, 20-40 mg every 4-6 hr or 1 mg IV slowly (repeat doses until heart rate slows); not indicated in patients with asthma or heart failure that is not rate related
Glucocorticoid therapy	Prednisone 20 mg bid
Supportive therapy	Intravenous fluids (depending on indication: glucose, electrolytes, multivitamins) Temperature control (cooling blankets, acetaminophen; avoid salicylates) O_2 if required Digitalis for heart failure and to slow ventricular response; pentobarbital for sedation Treatment of precipitating event (e.g., infection)

From Goldman L, Ausiello D, editors: Cecil textbook of medicine, *ed 22, Philadelphia, 2004, WB Saunders, p. 1401.*

Radioiodine is an effective therapy for Graves disease in children. In patients with severe thyrotoxicosis, euthyroidism should be restored with methimazole prior to radioablation in order to deplete the gland of preformed hormone and reduce the risk of thyrotoxic flare from radiation thyroiditis. If a patient is taking thionamides, they must be stopped 3-5 days before radioiodine administration to avoid inhibition of uptake. In children, the goal is to select a dose of radioiodine high enough to ensure complete ablation of thyroid tissue. Most centers obtain a diagnostic radioiodine uptake measurement before treatment and then use this to calculate a ^{131}I dose that delivers an absorbed thyroid dose of >150 μCi/g. Alternatively, an empirical fixed ^{131}I dose (usually 15 mCi) can be offered. The theoretical advantage of calculated doses is that they define for each individual patient the lowest administered dose that achieves the therapeutic target. This benefit is most important in small children, as the absorbed radiation dose to the bone marrow and other normal tissues is inversely proportional to body size. Based upon this concept and theoretical modeling of radiation exposure, current consensus guidelines recommend that ^{131}I therapy be avoided in very small children who are younger than 5 yr of age and that administered doses in children between 5 and 10 yr of age be <10 mCi. As with other Graves therapies, ^{131}I ablation has a low but obligate failure rate (5-20%). Patients with persistent hyperthyroidism more than 6 mo after their first ^{131}I therapy can be offered retreatment.

Thyroidectomy, a safe procedure when performed by an experienced surgeon, is done only after the patient has been brought to a euthyroid state. This may be accomplished with methimazole over 2-3 mo. After a euthyroid state has been attained, a saturated solution of potassium iodide, 3-5 drops 3 times per day, is added to the regimen for 2 wk before surgery to decrease the vascularity of the gland. In expert hands, complications of surgical treatment are rare and include hypoparathyroidism (transient or permanent) and paralysis of the vocal cords. The incidence of residual or recurrent hyperthyroidism or hypothyroidism depends on the extent of the surgery. Most recommend near-total thyroidectomy. The incidence of recurrence is low, and most patients become hypothyroid. Referral to a surgeon with extensive experience in thyroidectomy and a low personal complication rate is paramount.

The **ophthalmopathy** usually remits gradually and independently of the hyperthyroidism. Severe ophthalmopathy can require treatment with high-dose prednisone, orbital radiotherapy (of questionable value), or orbital decompression surgery. Cigarette smoking is a risk factor for thyroid eye disease and should be avoided or discontinued to avoid progression of eye involvement.

568.2 Congenital Hyperthyroidism

Stephen A. Huang and Stephen H. LaFranchi

ETIOLOGY AND PATHOGENESIS

Neonatal Graves disease is caused by transplacental passage of TRSAb, but the clinical onset, severity, and course may be modified by the concurrent presence of thyrotropin receptor–blocking antibody and by the transplacental passage of antithyroid drugs taken by the mother. Very high levels of TRSAb usually result in classic neonatal hyperthyroidism, but if the infant has been exposed to antithyroid drugs, onset of symptoms is delayed by 3-4 days as the maternally derived antithyroid drug is metabolized. If thyrotropin receptor–blocking antibody is also present, onset of hyperthyroid symptoms may be delayed for several weeks. The mothers of these infants have active Graves disease, Graves disease in remission, a past history of Graves disease managed by radioactive iodine ablation or surgery, or rarely hypothyroidism and a history of lymphocytic thyroiditis.

Neonatal hyperthyroidism occurs in only approximately 2% of infants born to mothers with a history of Graves disease. Fetal tachycardia and goiter can allow prenatal diagnosis and fetal ultrasound

surveillance is recommended in mothers with uncontrolled hyperthyroidism, elevated serum titers of TRSAb (thyrotropin-binding inhibitory immunoglobulin more than 3 times the upper limit of normal), or the history of a prior child with neonatal thyroid dysfunction. Unlike Graves disease at all other ages, neonatal hyperthyroidism affects boys as often as girls. One would expect twins to be equally affected, but 1 case reported 1 twin to be hyperthyroid and the other twin to be hypothyroid. Both eventually recovered to euthyroidism.

The disorder usually remits spontaneously within 6-12 wk but can persist longer, depending on the levels of TRSAb. Mild asymptomatic hyperthyroxinemia also occurs. Rarely, classic neonatal Graves disease does not remit but persists for several years or longer. These children have impressive family histories of Graves disease. In these infants, TRSAb transfer from the mother apparently blends with the infantile onset of autonomous Graves disease.

CLINICAL MANIFESTATIONS

Many of the infants are premature and appear to have intrauterine growth restriction. Most have goiters. The infant is extremely restless, irritable, and hyperactive and appears anxious and unusually alert. Microcephaly and ventricular enlargement may be present. The eyes are opened widely and appear exophthalmic (Fig. 568-3). There may be extreme tachycardia and tachypnea, and the temperature is elevated. In severely affected infants, there is a progression of symptoms; weight loss occurs despite a ravenous appetite, hepatosplenomegaly increases, and jaundice can occur. Severe hypertension and cardiac decompensation can occur. The infant can die if therapy is not instituted promptly. The serum levels of T_4 or free T_4 and T_3 are markedly elevated, and TSH is suppressed. Advanced bone age, frontal bossing with triangular facies, and cranial synostosis are common, especially in infants with persistent clinical manifestations of hyperthyroidism.

TREATMENT

Treatment of the neonate consists of oral administration of propranolol (1-2 mg/kg/24 hr, orally in 3 divided doses) and methimazole (0.25-1.0 mg/kg/24 hr given every 12 hr); saturated solution of potassium iodide (1 drop per day) may be added. When propranolol is used during pregnancy to treat thyrotoxicosis, it crosses the placenta and can cause respiratory depression in the newborn infant. If the thyrotoxic state is severe, parenteral fluid therapy and corticosteroids may be indicated. If heart failure occurs, digitalization is indicated. After a euthyroid state is reached, antithyroid medications should be gradually tapered to keep the infant euthyroid. Most cases remit by 3-4 mo of age.

Figure 568-3 **Twin boys with neonatal hyperthyroidism confirmed by abnormal thyroid function tests.** Clinical features include lack of subcutaneous tissue owing to a hypermetabolic state and a wide-eyed, anxious stare. They were given the diagnosis of neonatal Graves disease, but, in fact, their mother did not have Graves disease; they had persistent, not transient, hyperthyroidism. At age 8 yr, they were treated with radioiodine. They are now believed to have had some other form of neonatal hyperthyroidism, such as a constitutive activation of the thyroid-stimulating hormone receptor.

Occasionally, neonatal hyperthyroidism does not remit but persists into childhood. These patients can have an impressive family history of hyperthyroidism. Neonatal hyperthyroidism, without evidence for autoimmune disease in mother or infant, may be caused by a mutation in the *TSHR* gene that produced constitutive activation of the receptor. Neonatal hyperthyroidism has also been reported in patients with McCune-Albright syndrome, a result of an activating mutation of the α subunit of the G-protein. Under these circumstances, hyperthyroidism recurs when antithyroid drugs are discontinued; these children eventually must be treated with radioiodine or surgery.

PROGNOSIS

Advanced osseous maturation, microcephaly, and cognitive impairment occur when treatment is delayed. Intellectual development is normal in most treated infants with neonatal Graves disease, though some manifest neurocognitive problems from in utero hyperthyroidism. In some infants, in utero hyperthyroidism appears to suppress the hypothalamic-pituitary-thyroid feedback mechanism, and they develop permanent central hypothyroidism, requiring lifelong thyroid hormone treatment.

Chapter 569

Carcinoma of the Thyroid

Stephen A. Huang and
Stephen H. LaFranchi

EPIDEMIOLOGY

Carcinoma of the thyroid is rare in childhood; the annual incidence in children younger than 15 yr of age is approximately 2 in 100,000 cases, compared with an annual incidence at all ages around the world of 4-10 in 100,000 cases. In the last 2 decades, the incidence in children has increased 2-fold. Compared to adults, childhood thyroid cancers are characterized by dramatically higher rates of metastasis and recurrence. Despite being widespread at discovery, pediatric thyroid cancers usually have an indolent course and, with adequate treatment, most patients have a favorable outcome.

PATHOGENESIS

At all ages, the vast majority of differentiated thyroid cancers are of follicular cell origin and, in North America, **papillary carcinoma** (88%) is the most common subtype. Interestingly, while their histologic features are similar, the thyroid cancers of childhood are genetically distinct from their adult counterparts. Although up to 70% of adults with papillary thyroid cancer exhibit pathogenic somatic mutations in *BRAF* or *RAS,* these mutations are extremely rare in children with papillary cancer. In contrast, *RET-PTC* translocations, which result in chimeric proteins containing the tyrosine kinase domains of RET fused to the regulatory sequences of ubiquitously expressed genes such as *H1* and *ELE1,* are often found in childhood thyroid cancers. After papillary thyroid cancer, follicular cancer (10%) is the next most common type of childhood thyroid cancer. Medullary cancer (2%) and anaplastic thyroid cancers are relatively rare. Of note, only thyroid cancers of follicular cell origin (papillary and follicular carcinomas) respond to the adjunctive therapies of ^{131}I therapy and thyroid-stimulating hormone (TSH) suppression.

Up to 10% of cases of follicular cell–derived thyroid cancers are familial, and these are usually inherited in an autosomal dominant manner. Familial syndromes associated with an increased risk of thyroid neoplasia include Cowden syndrome (characterized by mucocutaneous

lesions, breast cancer, macrocephaly, and endometrial tumors) and familial adenomatous polyposis. Germline mutations in the *DICER-1* gene have also been recognized as a cause of thyroid neoplasia. The evaluation of a child with thyroid nodule should include a medical and family history to assess for features of these syndromes.

The thyroid gland of children is unusually sensitive to exposure to external radiation. There probably is no threshold dose; 1 Gy results in a 7.7 relative risk of thyroid cancer. In the past, approximately 80% of children with cancer of the thyroid had received inappropriate therapeutic irradiation of the neck and adjacent areas during infancy for benign conditions such as "enlarged" thymus, hypertrophied tonsils and adenoids, hemangiomas, nevi, eczema, tinea capitis, and "cervical adenitis." With the discontinuation of irradiation for benign conditions, this cause of thyroid cancer has vanished. The long-term survival of children who have received appropriate therapeutic irradiation of areas of the neck for neoplastic disease has made this cause of thyroid cancer and nodules increasingly prevalent; increased dose, younger age at time of treatment, and female sex are factors that increase the risk of thyroid cancer. Long-term risk data for cancer are sparse, but 15-50% of children who have received irradiation and chemotherapy for Hodgkin disease, leukemia, bone marrow transplantation, brain tumors, and other malignancies of the head and neck have elevated levels of TSH within the 1st yr of therapy, and 5-20% progress to hypothyroidism during the next 5-7 yr. Most large groups of treated children have a 10-30% incidence of benign thyroid nodules and an increased incidence of thyroid cancer. The latter begins to appear within 3-5 yr after radiation treatment and reaches a peak in 15-25 yr. It is unknown whether there is a period after which no more tumors develop. Administration of ^{131}I for diagnostic or therapeutic purposes does not appear to increase the risk of thyroid cancer.

Thyroid cancer has been reported in children with congenital goiter or ectopic thyroid tissue. In these patients, and also in children with autoimmune thyroiditis and hypothyroidism, chronic TSH stimulation appears to play a pathogenic role. It is unclear if the course of thyroid cancer differs in these patients compared to the general population. From a practical standpoint, nodules that are detected in the context of these disorders should be fully evaluated for cancer risk as in other children.

CLINICAL MANIFESTATIONS

The incidence of childhood thyroid cancer peaks in adolescence and girls are more commonly affected than boys. A painless nodule in the thyroid or in the neck is the usual presentation of disease. Rapid growth and large nodule size, firmness, fixation to adjacent tissues, hoarseness, dysphagia, and neck lymphadenopathy should heighten the concern for thyroid cancer. Cervical lymph node metastasis is common, so any unexplained cervical lymph node enlargement warrants examination of the thyroid. The lungs are the most common site of distant metastasis. There may be no clinical manifestations referable to them and formal pulmonary function testing may be normal even with widespread macroscopic metastases. Radiologically, they appear as diffuse miliary or nodular infiltrations, typically greatest in the posterior basal portions. They may be mistaken for tuberculosis, histoplasmosis, or sarcoidosis. Other sites of metastasis include the mediastinum, axilla, long bones, skull, and brain. Almost all children are euthyroid, but rarely, the carcinoma is functional and produces symptoms of hyperthyroidism.

DIAGNOSIS

As detailed in the following section, patients usually present with a neck mass and virtually all have a thyroid nodule of significant size upon ultrasound. While several imaging features are significantly associated with thyroid cancer risk, none have sufficient negative predictive value to forgo tissue diagnosis. Papillary thyroid cancer is characterized by nuclear abnormalities that are well identified by cytology and *fine-needle aspiration is the gold standard* in the evaluation of adults with nodules. Growing literature supports its use in the pediatric population. In most cases, operative pathology is required to confirm the diagnosis of thyroid cancer and to stage the extent of disease.

TREATMENT

The primary therapy for thyroid cancer is surgical resection. Because intrathyroidal spread is common in papillary thyroid, near-total thyroidectomy is the favored approach. Prior to this surgery, neck ultrasonography should be performed to screen for sonographically abnormal lymph nodes. Suspicious lymph nodes may be biopsied preoperatively to determine the appropriateness and extent of initial lymph node dissection. With the exception of very-low-risk patients, thyroidectomy is usually followed by adjunctive therapy with both TSH suppression (dosing levothyroxine to lower serum TSH and deprive residual thyroid cancer cells of this growth factor) and ^{131}I therapy (to ablate the normal thyroid remnant and/or to treat residual thyroid cancer).

PROGNOSIS

Although extrathyroidal invasion and distant metastasis are more common in the pediatric population, most children with thyroid cancer have a good outcome. Families should be counseled that the response to ^{131}I therapy is slow and that repeated treatments and years of care may be required to eliminate the disease. They should further be informed that many patients who are unable to achieve complete cure can be maintained in the well state with stable or slowly progressive cancer burden. For rare children with aggressive cancers that progress despite the optimization of conventional therapies, newer options, such as oral tyrosine kinase inhibitors, are available through research trials or on a compassionate basis. As with any cancer, psychosocial supports must be available, including access to social work and other mental health professionals.

Among solid tumors, thyroid cancer is unique in its capacity for late recurrence, sometimes occurring decades after initial presentation. For this reason, all children with thyroid cancer deserve lifelong monitoring for disease progression. For most patients, serum thyroglobulin is a sensitive and specific cancer marker. However, it must be recognized that about one fourth of patients have circulating antithyroglobulin autoantibodies that interfere with standard thyroglobulin assays and produce artifactually low measurements. Because of this, antithyroglobulin autoantibodies must always be measured whenever serum thyroglobulin is assayed to confirm the latter's reliability. As most thyroid cancer recurrences are local, surveillance should include serial neck ultrasounds. Patients with higher recurrence risk or documentation of distant metastases typically benefit from additional anatomic imaging studies and from extended surveillance studies performed during TSH stimulation.

Bibliography is available at Expert Consult.

569.1 Solitary Thyroid Nodule

Stephen A. Huang and Stephen H. LaFranchi

The frequency of thyroid nodules increases with age. While sonographically detectable nodules are present in 19-67% of randomly selected adults, the estimated frequency of nodules in children is only 0.05-2.0%. Although early pediatric series cited extremely high rates of cancer in thyroid nodules (up to 70%), more recent studies of children report lower cancer prevalence (around 20-26%) that is similar to the 5-15% prevalence observed in adults. Thus, when a thyroid nodule is discovered in a child, parents should be counseled that the majority of nodules are benign.

Benign disorders that can occur as a solitary thyroid mass include benign adenomatous or colloid nodules, as well as a variety of congenital cysts (Table 569-1). A suddenly appearing or rapidly enlarging thyroid mass can indicate hemorrhage into a cyst or benign adenoma. When evaluating a child with a thyroid nodule, it is helpful to begin by measuring serum TSH.

In rare patients who present with a suppressed serum TSH, a thyroid scan, preferably using ^{123}I or ^{99m}Tc-pertechnetate, should be performed to assess the possibility of a benign hyperfunctioning thyroid nodule. All other patients should proceed directly to ultrasound and, if a

Table 569-1	Etiologic Classification of Solitary Thyroid Nodules

Lymphoid follicle, as part of chronic lymphocytic thyroiditis
Thyroid developmental anomalies
  Intrathyroidal thyroglossal duct cyst
Thyroid abscess (acute suppurative thyroiditis)
Simple cyst
  Neoplasms
    Benign
    Colloid (adenomatous) nodule
    Follicular adenoma
    Toxic adenoma
    Nonthyroidal (e.g., lymphohemangioma)
  Malignant
    Papillary carcinoma
    Follicular carcinoma
    Mixed papillary-follicular carcinoma
    Undifferentiated (anaplastic)
    Medullary carcinoma
  Nonthyroidal
    Lymphoma
    Teratoma

discrete nodule(s) of significant size is documented by this imaging, it should be biopsied by ultrasound-guided fine-needle aspiration (FNA). FNA cytology may be interpreted as benign, positive for papillary thyroid cancer, indeterminate, or inadequate. When an initial biopsy is nondiagnostic, an adequate sample can usually be obtained by repeating aspiration. Multiple categorization systems exist and most North American centers follow the Bethesda Criteria for interpretation of thyroid cytology. The predictive value of thyroid FNA varies between institutions. In most high-volume centers, the "positive for papillary thyroid cancer" category corresponds to a >98% likelihood of cancer and, in that context, near-total thyroidectomy is appropriate. In children with indeterminate cytology and unilateral nodules, lobectomy is commonly performed. This is followed by completion thyroidectomy if lobectomy pathology shows a significant cancer. Patients with cytologically benign nodules can be offered the option of deferring surgery so long as they are willing to commit to careful surveillance with serial neck imaging.

Bibliography is available at Expert Consult.

569.2 Medullary Thyroid Carcinoma

Stephen H. LaFranchi

Medullary thyroid carcinoma (MTC) arises from the parafollicular cells (C cells) of the thyroid and accounts for approximately 2% of thyroid malignancies in children. The majority of MTC cases are sporadic, but approximately 25% are familial, autosomal dominant disorders. Hereditary MTC is divided into 3 distinct syndromes: multiple endocrine neoplasia type 2A (MEN2A), multiple endocrine neoplasia type 2B (MEN2B), and familial MTC. In contrast to the somatic mutations associated with sporadic MTC, germline mutations in the *RET* protooncogene on chromosome 10q11.2 are inheritable and can cause familial medullary thyroid cancer. Once an index case is diagnosed in a family, it is important to pinpoint the specific *RET* mutation and then genotype all 1st-degree relatives for the mutation. Many *RET* mutations have been well studied and strong genotype–phenotype associations have been established to predict disease aggressiveness. In carriers, thyroidectomy before the MTC has spread outside the gland represents the best chance for a cure and the patient's specific genotype can be used to guide the timing of prophylactic surgery.

The most common presentation of sporadic MTC is an asymptomatic, palpable thyroid nodule. When the tumor occurs sporadically, it is usually unicentric, but in the familial form, it is usually multicentric, and it begins as hyperplasia of parafollicular cells. The diagnosis of MTC can often be made through routine FNA cytology, but documentation of high calcitonin in an FNA washing or in the patients' serum is helpful as confirmation. The diagnosis of MTC warrants genetic testing for *RET* mutation and screens for MEN2-associated pheochromocytoma and hyperparathyroidism should be obtained prior to anesthesia for thyroidectomy. No clinically recognizable manifestations result from the elevated serum levels of calcitonin or CEA. Nonetheless, these tests are helpful in screening and monitoring therapy.

MULTIPLE ENDOCRINE NEOPLASIA, TYPE 2A

MEN2A is an autosomal dominant disorder characterized by MTC, pheochromocytoma, and parathyroid hyperplasia. At least 19 different specific missense mutations of exon 10 or 11 of the extracellular domain of the *RET* gene have been described for MEN2A and for cases of familial MTC. DNA analysis permits unambiguous identification of carriers of the *RET* protooncogene mutation. Penetrance of MTC is close to 100%, but there is much variability in the other manifestations of MEN2A. C-cell hyperplasia or MTC usually appears earlier than pheochromocytoma. Pheochromocytomas are often bilateral and may be multiple. Adrenal medullary hyperplasia is known to precede pheochromocytoma, but the detectable latent period is short. Hypercalcemia is a late manifestation and indicates hyperparathyroidism. The parathyroid glands might reveal chief-cell hyperplasia or only hypercellularity.

MULTIPLE ENDOCRINE NEOPLASIA, TYPE 2B

MEN2B is an autosomal dominant disorder characterized by MTC and pheochromocytomas but not hyperparathyroidism. The distinguishing feature of MEN2B, also called the **mucosal neuroma syndrome,** is the occurrence of multiple neuromas and a characteristic phenotype that includes Marfan-like facies. A missense mutation of the *RET* protooncogene in exon 16, the tyrosine catalytic domain of *RET,* is found in 93% of families; all patients have had the same point mutation.

The neuromas most often occur on the tongue, buccal mucosa, lips, and conjunctivae. Peripheral neurofibromas and café-au-lait patches may be present, and intestinal ganglioneuromatosis is common. Diffuse proliferation of nerves and ganglion cells is found in mucosal, submucosal, myenteric, and subserosal plexus involving the small and large bowel as well as the esophagus. The patients may be tall, with arachnodactyly and a Marfan-like appearance. Scoliosis, pectus excavatum, pes cavus, and muscular hypotonia are common. The eyelids may be thickened and everted, the lips patulous and blubbery, the jaw prognathic. Feeding difficulties, poor sucking, diarrhea, constipation, and failure to thrive can begin in infancy or early childhood, many years before the appearance of neuromas or endocrine symptoms.

TREATMENT

Total thyroidectomy is indicated for all children who are shown by genetic studies to carry high-risk *RET* mutations. Recognition of familial forms of this tumor is critical to the early diagnosis and intervention in children at risk. MTC develops at an earlier age in patients with MEN2B and is more aggressive than in MEN2A. MTC has been seen in a 6 mo old child with MEN2B and in a 3 yr old child with MEN2A. In MEN2A, there is genotype–phenotype correlation between the specific mutation and the onset of C-cell hyperplasia or MTC. With codon 634 mutations, MTC occurs at an early age, whereas with mutations at codons 618, 620, and 804, MTC tends to occur at a later age. In young children, recommendations for the timing of prophylactic thyroidectomy are available for the common *RET* mutations. All these children should be screened for pheochromocytoma before surgery. Monitoring the serum levels of calcitonin and carcinoembryonic antigen is useful in following the course of the disease after operation and in detecting metastatic lesions. Periodic screening for the development of pheochromocytoma and hyperparathyroidism is indicated. Metastases to the regional lymph nodes and to the liver can occur. Early clinic studies support that prophylactic thyroidectomy is effective in preventing death from MTC.

Section 3

Disorders of the Parathyroid Gland

Chapter 570

Hormones and Peptides of Calcium Homeostasis and Bone Metabolism

Daniel A. Doyle

Parathyroid hormone (PTH) and vitamin D are the principal regulators of calcium homeostasis (see Chapters 48 and 694). Calcitonin and PTH-related peptide (PTHrP) are important primarily in the fetus.

PARATHYROID HORMONE

PTH is an 84-amino-acid chain (95 kDa), but its biologic activity resides in the first 34 residues. In the parathyroid gland, a pre-pro-PTH (115-amino-acid chain) and a pro-PTH (90 amino acids) are synthesized. Pre-pro-PTH is converted to pro-PTH and pro-PTH to PTH. PTH (consisting of amino acids 1-84) is the major secretory product of the gland, but it is rapidly cleaved in the liver and kidney into smaller COOH-terminal, mid-region, and NH_2-terminal fragments.

The occurrence of these fragments in serum has led to the development of a variety of assays. The 1-34 aminoterminal (N-terminus) fragments possess biologic activity but are present in low amounts in the circulation; assay of these fragments is most useful for detecting acute secretory changes. The carboxyterminal (C-terminus) and midregion fragments, although biologically inert, are cleared more slowly from the circulation and represent 80% of plasma immunoreactive PTH; concentrations of the C-terminal fragment are 50-500 times the level of the active hormone. The C-terminal assays are effective in detecting hyperparathyroidism, but because C-terminal fragments are removed from the circulation by glomerular filtration, these assays are less useful for evaluating the secondary hyperparathyroidism characteristic of renal disease. Only certain sensitive radioimmunoassays for PTH can differentiate the subnormal concentrations that occur in hypoparathyroidism from normal levels.

When serum levels of calcium fall, the signal is transduced through the calcium-sensing receptor, and secretion of PTH increases (Fig. 570-1). PTH stimulates activity of 1α-hydroxylase in the kidney, enhancing production of 1,25-dihydroxycholecalciferol, also written $1,25(OH)_2D_3$. The increased level of $1,25(OH)_2D_3$ induces synthesis of a calcium-binding protein (calbindin-D) in the intestinal mucosa, with resultant absorption of calcium. PTH also mobilizes calcium by directly enhancing bone resorption, an effect that requires $1,25(OH)_2D_3$. The effects of PTH on bone and kidney are mediated through binding to specific receptors on the membranes of target cells and through activation of a transduction pathway involving a G-protein coupled to the adenylate cyclase system (see Chapter 572).

The calcium-sensing receptor regulates the secretion of PTH and the reabsorption of calcium by the renal tubules in response to alterations in serum calcium concentrations. The gene for the receptor is located on chromosome 3q13.3-q21 and encodes a cell surface protein that is expressed in parathyroid glands and kidneys and belongs to the family of G-protein–coupled receptors. In the normally functioning calcium-sensing receptor, hypocalcemia induces increased secretion of PTH and hypercalcemia depresses PTH secretion. Loss-of-function mutations cause an increased set point with respect to serum calcium, resulting in hypercalcemia and in the conditions of **familial hypocalciuric hypercalcemia** and neonatal severe hyperparathyroidism. Acquired hypocalciuric hypercalcemia may be a result of autoantibodies to the calcium-sensing receptor and manifests with hypercalcemia and hyperparathyroidism. Gain-of-function mutations result in depressed secretion of PTH in response to hypocalcemia, leading to the syndrome of familial hypocalcemia with hypercalciuria (see Fig. 570-1).

PARATHYROID HORMONE–RELATED PEPTIDE

PTHrP is homologous to PTH only in the first 13 amino acids of its amino terminus, 8 of which are identical to PTH. Its gene is on the short arm of chromosome 12 and that of PTH is on the short arm of chromosome 11.

PTHrP, like PTH, activates PTH receptors in kidney and bone cells and increases urinary cyclic adenosine monophosphate and renal production of $1,25(OH)_2D_3$. It is produced in almost every type of cell of the body, including every tissue of the embryo at some stage of development. PTHrP is critical for normal fetal development. Inactivating mutations of the receptor for PTH/PTHrP result in a lethal bone disorder characterized by short limbs and markedly advanced bone maturation known as *Blomstrand chondrodysplasia* (see Fig. 570-1). PTHrP appears to have a paracrine or autocrine role because serum levels are low except in a few clinical situations. Cord blood contains levels of PTHrP that are 3-fold higher than in serum from adults; it is produced by the fetal parathyroid glands and appears to be the main agent stimulating maternal-fetal calcium transfer. PTHrP appears to be essential for normal skeletal maturation of the fetus, which requires 30 g of calcium during a normal gestation. During pregnancy, maternal absorption of calcium increases from about 150 mg daily to 400 mg during the 2nd trimester.

As in cord blood, PTHrP levels are increased during lactation and in patients with benign breast hypertrophy. Breast milk and pasteurized bovine milk have levels of PTHrP that are 10,000 times higher than those of normal plasma. Most instances of the hormonal hypercalcemia syndrome of malignancy are caused by elevated concentrations of PTHrP.

VITAMIN D

See Chapter 51.

CALCITONIN

Calcitonin is a 32-amino-acid polypeptide. Its gene is on chromosome 11p and is tightly linked to that of PTH. The gene for calcitonin encodes 3 peptides: calcitonin, a 21-amino-acid carboxyterminal flanking peptide (katacalcin), and a calcitonin gene–related peptide. Katacalcin and calcitonin are cosecreted in equimolar amounts by the parafollicular cells (C cells) of the thyroid gland. Calcitonin appears to be of little consequence in children and adults because very high levels in patients with medullary carcinoma of the thyroid (a tumor arising from the C cells) do not cause hypercalcemia. In the fetus, however, circulating levels are high and appear to augment bone metabolism and skeletal growth; these high levels are probably stimulated by the normally high fetal calcium levels. Unlike the high levels in cord blood and circulating concentrations in young children, levels in older children and adults are low. Infants and children with congenital hypothyroidism (and presumed deficiency of C cells) have lower levels of calcitonin than do normal children.

Its action appears to be independent of PTH and vitamin D. Its main biologic effect appears to be the inhibition of bone resorption by decreasing the number and activity of bone-resorbing osteoclasts. This action of calcitonin is the rationale for its use in treatment of Paget disease. Calcitonin is synthesized in other organs, such as the gastrointestinal tract, pancreas, brain, and pituitary. In these organs, calcitonin is thought to behave as a neurotransmitter to impose a local inhibitory effect on cell function.

Chapter 571

Hypoparathyroidism

Daniel A. Doyle

ETIOLOGY

Hypocalcemia is common in neonates between 12 and 72 hr of life, especially in premature infants, in infants with asphyxia, and in infants of diabetic mothers (early neonatal hypocalcemia; see Chapter 106; Table 571-1 and Fig. 571-1). After the 2nd to 3rd day and during the 1st wk of life, the type of feeding also is a determinant of the level of serum calcium (late neonatal hypocalcemia). The role played by the parathyroid glands in these hypocalcemic infants remains to be clarified, although functional immaturity of the parathyroid glands is invoked as 1 pathogenetic factor. In a group of infants with transient idiopathic hypocalcemia (1-8 wk of age), serum levels of parathyroid hormone (PTH) are significantly lower than those in normal infants. It is possible that the functional immaturity is a manifestation of a delay in development of the enzymes that convert glandular PTH to secreted PTH; other mechanisms are possible.

APLASIA OR HYPOPLASIA OF THE PARATHYROID GLANDS

Aplasia or hypoplasia of the parathyroid glands is often associated with the **DiGeorge/velocardiofacial syndrome** (see Fig. 570-1). This syndrome occurs in 1 in 4,000 newborns. In 90% of patients, the condition is caused by a deletion of chromosome 22q11.2. Approximately 25%

Table 571-1 Causes of Hypocalcemia

I. Neonatal
  A. Maternal Disorders
    Diabetes mellitus
    Toxemia of pregnancy
    Vitamin D deficiency
    High intake of alkali or magnesium sulfate
    Use of anticonvulsants
    Hyperparathyroidism
  B. Neonatal Disorders
    Low birthweight: prematurity, intrauterine growth restriction
    Peripartum asphyxia, sepsis, critical illness
    Hyperbilirubinemia, phototherapy, exchange transfusion
    Hypomagnesemia, hypermagnesemia
    Acute/chronic renal failure
    Nutrients/medications: high phosphate intake, fatty acids, phytates, bicarbonate infusion, citrated blood, anticonvulsants, aminoglycosides
    Hypoparathyroidism
    Vitamin D deficiency or resistance
    Osteopetrosis type II
II. Hypoparathyroidism
  A. Congenital
    1. Transient neonatal
    2. Congenital hypoparathyroidism
      a. Familial isolated hypoparathyroidism
        (1) Autosomal recessive hypoparathyroidism (GCMB, PTH)
        (2) Autosomal dominant hypoparathyroidism (CaSR)
        (3) X-linked hypoparathyroidism *(SOX3)*
      b. DiGeorge syndrome *(TBX1)*
      c. Sanjad-Sakati syndrome (short stature, retardation, dysmorphism; HRD); Kenny-Caffey syndrome 1 (short stature, medullary stenosis) *(TBCE)*
      d. Barakat syndrome (sensorineural deafness, renal dysplasia; HDR) *(GATA3)*
      e. Lymphedema-hypoparathyroidism-nephropathy, nerve deafness
      f. Mitochondrial fatty acid disorders (Kearns-Sayre, Pearson, MELAS)
    3. Insensitivity to PTH
      a. Blomstrand chondrodysplasia *(PTHR1)*
      b. Pseudohypoparathyroidism type IA *(GNAS)*
        Pseudohypoparathyroidism type IB
        Pseudohypoparathyroidism type IC
        Pseudohypoparathyroidism type II
        Pseudopseudohypoparathyroidism
      c. Acrodysostosis with hormone resistance *(PRKAR1A)*
      d. Hypomagnesemia
    4. CaSR-activating mutation
      a. Sporadic
      b. Autosomal dominant (G protein subunit α11 mutation)
  B. Acquired
    1. Autoimmune polyglandular syndrome type I (*AIRE* gene mutation)
    2. Activating antibodies to the CaSR
    3. Postsurgical, radiation destruction
    4. Infiltrative—excessive iron (hemochromatosis, thalassemia) or copper (Wilson disease) deposition; granulomatous inflammation, neoplastic invasion; amyloidosis, sarcoidosis
    5. Maternal hyperparathyroidism
    6. Hypomagnesemia/hypermagnesemia
III. Vitamin D Deficiency
IV. Other Causes of Hypocalcemia
  A. Calcium Deficiency
    1. Nutritional deprivation
    2. Hypercalciuria
  B. Disorders of Magnesium Homeostasis
    1. Congenital hypomagnesemia
    2. Acquired
      a. Acute renal failure
      b. Chronic inflammatory bowel disease, intestinal resection
      c. Diuretics
  C. Hyperphosphatemia
    1. Renal failure
    2. Phosphate administration (intravenous, oral, rectal)
    3. Tumor cell lysis
    4. Muscle injuries (crush, rhabdomyolysis)
  D. Miscellaneous
    1. Hypoproteinemia
    2. Hyperventilation
    3. Drugs: furosemide, aminoglycosides, bisphosphonates, calcitonin, anticonvulsants, ketoconazole, antineoplastic agents (plicamycin, asparaginase, cisplatinum, cytosine arabinoside, doxorubicin), citrated blood products
    4. Hungry bone syndrome
    5. Acute and critical illness: sepsis, acute pancreatitis, toxic shock
      a. Organic acidemia: propionic, methylmalonic, isovaleric

HDR, hypoparathyroidism, sensorineural deafness, and renal anomaly; HRD, hypoparathyroidism, retardation, dysmorphism; MELAS, mitochondrial encephalomyopathy with lactic acidosis and stroke-like episode; PTH, parathyroid hormone.

of these patients inherit the chromosomal abnormality from a parent. Neonatal hypocalcemia occurs in 60% of affected patients, but it is transitory in the majority; hypocalcemia can recur or can have its onset later in life. Associated abnormalities of the third and fourth pharyngeal pouches are common; these include conotruncal defects of the heart in 25%, velopharyngeal insufficiency in 32%, cleft palate in 9%, renal anomalies in 35%, and aplasia of the thymus with severe immunodeficiency in 1%. This syndrome has also been reported in a small number of patients with a deletion of chromosome 10p13, in infants of diabetic mothers, and in infants born to mothers treated with retinoic acid for acne early in pregnancy.

X-LINKED RECESSIVE HYPOPARATHYROIDISM

Familial clusters of hypoparathyroidism with various patterns of transmission have been described. In 2 large North American pedigrees, this disorder appears to be transmitted by an X-linked recessive gene located on Xq26-q27. In these families, the onset of afebrile seizures characteristically occurs in infants from 2 wk to 6 mo of age. The absence of parathyroid tissue after detailed examination of a boy with this condition suggests a defect in embryogenesis.

AUTOSOMAL RECESSIVE HYPOPARATHYROIDISM WITH DYSMORPHIC FEATURES

Autosomal recessive hypoparathyroidism with dysmorphic features has been described in Middle Eastern children. Parental consanguinity occurred for almost all of several dozen affected patients. Profound hypocalcemia occurs early in life, and dysmorphic features include microcephaly, deep-set eyes, beaked nose, micrognathia, and large floppy ears. Intrauterine and postnatal growth restriction are severe, and cognitive impairment is common. The putative gene is on chromosome 1q42-43. The autosomal recessive form of hypoparathyroidism that occurs with type I polyglandular autoimmune disease is described subsequently. In a few patients with autosomal recessive inheritance of isolated hypoparathyroidism, mutations of the *PTH* gene have been found.

HYPOPARATHYROIDISM, SENSORINEURAL DEAFNESS, AND RENAL ANOMALY SYNDROME

Hypoparathyroidism, sensorineural deafness, and renal anomaly occur owing to mutations of the *GATA3* gene. The protein encoded by this gene is essential in the development of the parathyroids, auditory system, and kidneys. The *GATA3* gene is located at chromosome 10p14 and is nonoverlapping with the DiGeorge critical region at 10p13 (see Fig. 570-1).

SUPPRESSION OF NEONATAL PARATHYROID HORMONE SECRETION BECAUSE OF MATERNAL HYPERPARATHYROIDISM

Neonatal PTH secretion can be suppressed by maternal hyperparathyroidism, resulting in transient hypocalcemia in the newborn infant. It appears that neonatal hypocalcemia results from suppression of the fetal parathyroid glands by exposure to elevated levels of calcium in maternal and hence fetal serum. Tetany usually develops within 3 wk but may be delayed by 1 mo or more if the infant is breastfed. Hypocalcemia can persist for weeks or months. When the cause of hypocalcemia in an infant is unknown, measurements of calcium, phosphorus, and PTH should be obtained from the mother. Most affected mothers are asymptomatic, and the cause of their hyperparathyroidism is usually a parathyroid adenoma.

AUTOSOMAL DOMINANT HYPOPARATHYROIDISM

Patients with autosomal dominant hypoparathyroidism have an activating (gain-of-function) mutation of the Ca^{2+}-sensing receptor, forcing the receptor to an “on” state with subsequent depression of PTH secretion even during hypocalcemia. The patients have hypercal-

ciuria. The hypocalcemia is usually mild and might not require treatment beyond childhood (see Fig. 570-1).

HYPOPARATHYROIDISM ASSOCIATED WITH MITOCHONDRIAL DISORDERS

Mitochondrial DNA mutations in Kearns-Sayre syndrome, MELAS (myopathy, encephalopathy, lactic acidosis, and stroke-like episodes) syndrome, and in mitochondrial trifunctional protein–deficiency syndrome are associated with hypoparathyroidism. A diagnosis of mitochondrial cytopathy should be considered in patients with unexplained symptoms, such as ophthalmoplegia, sensorineural hearing loss, cardiac conduction disturbances, and tetany (see Fig. 570-1).

SURGICAL HYPOPARATHYROIDISM

Removal or damage of the parathyroid glands can complicate thyroidectomy. Hypoparathyroidism has developed even when the parathyroid glands have been identified and left undisturbed at the time of operation. This may be the result of interference with the blood supply or of postoperative edema and fibrosis. Symptoms of tetany can occur abruptly postoperatively and may be temporary or permanent. In some instances, symptoms develop insidiously and go undetected until months after thyroidectomy. Occasionally, the first evidence of surgical hypoparathyroidism may be the development of cataract. The status of parathyroid function should be carefully monitored in all patients undergoing thyroidectomy.

Deposition of iron pigment or of copper in the parathyroid glands (thalassemia, Wilson disease) can produce hypoparathyroidism.

AUTOIMMUNE HYPOPARATHYROIDISM

An autoimmune mechanism for hypoparathyroidism is strongly suggested by the finding of parathyroid antibodies and by its frequent association with other autoimmune disorders or organ-specific antibodies. Autoimmune hypoparathyroidism is often associated with Addison disease and chronic mucocutaneous candidiasis. The association of at least 2 of these 3 conditions has been tentatively classified as **autoimmune polyglandular disease type I.** It is also known as autoimmune polyendocrinopathy, candidiasis, and ectodermal dystrophy (APECED). This syndrome is inherited in an autosomal recessive fashion and is not related to any single human leukocyte antigen–associated haplotype. One third of patients with this syndrome have all 3 components; 66% have only 2 of 3 conditions. The candidiasis almost always precedes the other disorders (70% of cases occur in children younger than 5 yr of age); the hypoparathyroidism (90% of cases occur after 3 yr of age) usually occurs before Addison disease (90% of cases occur after 6 yr of age). A variety of other disorders, including alopecia areata or totalis, malabsorption disorder, pernicious anemia, gonadal failure, chronic active hepatitis, vitiligo, and insulin-dependent diabetes, occurs at various times. Some of these associations might not appear until adult life. Autoimmune thyroid disease is a rare concomitant finding.

Affected siblings can have the same or different constellations of disorders (hypoparathyroidism, Addison disease). The disorder is exceptionally prevalent among Finns and Iranian Jews. The gene for this disorder is designated *AIRE* (autoimmune regulator); it is located on chromosome 21q22. It appears to be a transcription factor that plays an essential role in the development of immunologic tolerance. Patients with Addison disease as part of polyendocrinopathy syndrome type I have demonstrated adrenal-specific autoantibody reactivity directed against the side-chain cleavage enzyme.

IDIOPATHIC HYPOPARATHYROIDISM

The term *idiopathic hypoparathyroidism* should be reserved for the small residuum of children with hypoparathyroidism for whom no causative mechanism can be defined. Most children in whom onset of hypoparathyroidism occurs after the 1st few yr of life have an **autoimmune condition.** Autoantibodies to the extracellular domain of the calcium-sensing receptor have been identified in some patients with acquired hypoparathyroidism. One should always consider incomplete forms of DiGeorge syndrome or an activating calcium-sensing receptor mutation in the differential diagnosis.

Clinical Manifestations

There is a spectrum of parathyroid deficiencies with clinical manifestations varying from no symptoms to those of complete and long-standing deficiency. Mild deficiency may be revealed only by appropriate laboratory studies. Muscular pain and cramps are early manifestations; they progress to numbness, stiffness, and tingling of the hands and feet. There may be only a positive Chvostek or Trousseau sign or laryngeal and carpopedal spasms. Convulsions with or without loss of consciousness can occur at intervals of days, weeks, or months. These episodes can begin with abdominal pain, followed by tonic rigidity, retraction of the head, and cyanosis. Hypoparathyroidism is often mistaken for epilepsy. Headache, vomiting, increased intracranial pressure, and papilledema may be associated with convulsions and might suggest a brain tumor.

In patients with long-standing hypocalcemia, the teeth erupt late and irregularly. Enamel formation is irregular, and the teeth may be unusually soft. The skin may be dry and scaly, and the nails might have horizontal lines. Mucocutaneous candidiasis, when present, antedates the development of hypoparathyroidism; the candidal infection most often involves the nails, the oral mucosa, the angles of the mouth, and less often, the skin; it is difficult to treat.

Cataracts in patients with long-standing untreated disease are a direct consequence of hypoparathyroidism; other autoimmune ocular disorders such as keratoconjunctivitis can also occur. Manifestations of Addison disease, lymphocytic thyroiditis, pernicious anemia, alopecia areata or totalis, hepatitis, and primary gonadal insufficiency may also be associated with those of hypoparathyroidism.

Permanent physical and mental deterioration occurs if initiation of treatment is long delayed.

Laboratory Findings

The serum calcium level is low (5-7 mg/dL), and the phosphorus level is elevated (7-12 mg/dL). Blood levels of ionized calcium (usually approximately 45% of the total) more nearly reflect physiologic adequacy but also are low. The serum level of alkaline phosphatase is normal or low, and the level of $1,25(OH)_2D_3$ is usually low, but high levels have been found in some children with severe hypocalcemia. The level of magnesium is normal but should always be checked in hypocalcemic patients. Levels of PTH are low when measured by immunometric assay. Radiographs of the bones occasionally reveal an increased density limited to the metaphyses, suggesting heavy metal poisoning, or an increased density of the lamina dura. Radiographs or CT scans of the skull can reveal calcifications in the basal ganglia. There is a prolongation of the QT interval on the electrocardiogram, which disappears when the hypocalcemia is corrected. The electroencephalogram usually reveals widespread slow activity; the tracing returns to normal after the serum calcium concentration has been within the normal range for a few weeks, unless irreversible brain damage has occurred or unless the parathyroid insufficiency is associated with epilepsy. When hypoparathyroidism occurs concurrently with Addison disease, the serum level of calcium may be normal, but hypocalcemia appears after effective treatment of the adrenal insufficiency.

Treatment

Emergency treatment of neonatal tetany consists of intravenous injections of 5-10 mL or 1-3 mg/kg of a 10% solution of calcium gluconate (elemental calcium 9.3 mg/mL) at the rate of 0.5-1.0 mL/min while the heart rate is monitored and a total dose not to exceed 20 mg of elemental calcium/kg. Additionally, 1,25-dihydroxycholecalciferol (calcitriol) should be given. The initial dosage is 0.25 µg/24 hr; the maintenance dosage ranges from 0.01-0.10 µg/kg/24 hr to a maximum of 1-2 µg/24 hr. Calcitriol has a short half-life and should be given in 2 equal divided doses; it has the advantages of rapid onset of effect (1-4 days) and rapid reversal of hypercalcemia after discontinuation in the

event of overdosage (calcium levels begin to fall in 3-4 days). Calcitriol is supplied as an oral solution.

An adequate intake of calcium should be ensured. Supplemental calcium can be given in the form of calcium gluconate or calcium glubionate to provide 800 mg of elemental calcium daily, but it is rarely essential. Foods with high phosphorus content such as milk, eggs, and cheese should be reduced in the diet.

Clinical evaluation of the patient and frequent determinations of the serum calcium levels are indicated in the early stages of treatment to determine the requirement for calcitriol or vitamin D_2. If hypercalcemia occurs, therapy should be discontinued and resumed at a lower dose after the serum calcium level has returned to normal. In long-standing cases of hypercalcemia, repair of cerebral and dental changes is not likely. Pigmentation, lowering of blood pressure, or weight loss can indicate adrenal insufficiency, which requires specific treatment. *Patients with autosomal dominant hypocalcemic hypercalciuria can develop nephrocalcinosis and renal impairment if treated with vitamin D.*

Differential Diagnosis

Magnesium deficiency must be considered in patients with unexplained hypocalcemia. Concentrations of serum magnesium <1.5 mg/dL (1.2 mEq/L) are usually abnormal. Familial hypomagnesemia with secondary hypocalcemia has been reported in approximately 50 patients, most of whom developed tetany and seizures at 2-6 wk of age. Administration of calcium is ineffective, but administration of magnesium promptly corrects both calcium and magnesium levels. Oral supplements of magnesium are necessary to maintain levels of magnesium in the normal range. Two genetic forms have been described. One is caused by an autosomal recessive gene on chromosome 9, resulting in a specific defect in absorption of magnesium. The other is caused by an autosomal dominant gene on chromosome 11q23, resulting in renal loss of magnesium.

Hypomagnesemia also occurs in malabsorption syndromes such as Crohn disease and cystic fibrosis. Patients with autoimmune polyglandular disease type I and hypoparathyroidism can also have concurrent steatorrhea and low magnesium levels. Therapy with aminoglycosides causes hypomagnesemia by increasing urinary losses.

It is not clear how low levels of magnesium lead to hypocalcemia. Evidence suggests that hypomagnesemia impairs release of PTH and induces resistance to the effects of the hormone, but other mechanisms also may be operative.

Poisoning with inorganic phosphate leads to hypocalcemia and tetany. Infants administered large doses of inorganic phosphates, either as laxatives or as sodium phosphate enemas, have had sudden onset of tetany, with serum calcium levels <5 mg/dL and markedly elevated levels of phosphate. Symptoms are quickly relieved by intravenous administration of calcium. The mechanism of the hypocalcemia is not clear (see Chapter 55.6).

Hypocalcemia can occur early in the course of treatment of acute lymphoblastic leukemia. Hypocalcemia is usually associated with hyperphosphatemia resulting from destruction of lymphoblasts.

Episodic symptomatic hypocalcemia occurs in the **Kenny-Caffey syndrome,** which is characterized by medullary stenosis of the long bones, short stature, delayed closure of the fontanel, delayed bone age, and eye abnormalities. Idiopathic hypoparathyroidism and abnormal PTH levels have been found. Autosomal dominant and autosomal recessive modes of inheritance have been reported. Mutations of the *TBCE* gene (1q 43-44) perturb microtubule organization in diseased cells.

Chapter 572

Pseudohypoparathyroidism (Albright Hereditary Osteodystrophy)

Daniel A. Doyle

In contrast to the situation in hypoparathyroidism, in pseudohypoparathyroidism (PHP) the parathyroid glands are normal or hyperplastic and they can synthesize and secrete parathyroid hormone (PTH). Serum levels of immunoreactive PTH are elevated even when the patient is hypocalcemic and may be elevated when the patient is normocalcemic. Neither endogenous nor administered PTH raises the serum levels of calcium or lowers the levels of phosphorus. The genetic defects in the **hormone receptor adenylate cyclase system** are classified into various types depending on the phenotypic and biochemical findings.

TYPE IA

Type Ia accounts for the majority of patients with PHP. Affected patients have a genetic defect of the α subunit of the stimulatory guanine nucleotide-binding protein ($G_s\alpha$). This coupling factor is required for PTH bound to cell surface receptors to activate cyclic adenosine monophosphate (cAMP). Heterogeneous mutations of the $G_s\alpha$ gene have been documented; the gene is located on chromosome 20q13.2. Deficiency of the $G_s\alpha$ subunit is a generalized cellular defect and accounts for the association of other endocrine disorders with type Ia PHP. The defect is inherited as an autosomal dominant trait, and the paucity of father-to-son transmissions is thought to be a result of decreased fertility in males.

Tetany is often the presenting sign. Affected children have a short, stocky build and a round face. Brachydactyly with dimpling of the dorsum of the hand is usually present. The 2nd metacarpal is involved least often. As a result, the index finger occasionally is longer than the middle finger. Likewise, the 2nd metatarsal is only rarely affected. There may be other skeletal abnormalities such as short and wide phalanges, bowing, exostoses, and thickening of the calvaria. These patients often have calcium deposits and metaplastic bone formation subcutaneously. Moderate degrees of cognitive impairment, calcification of the basal ganglia, and lenticular cataracts are common in patients whose disease is diagnosed late.

Some members of affected kindreds may have the usual anatomic stigmata of PHP, but serum levels of calcium and phosphorus are normal despite reduced $G_s\alpha$ activity; however, PTH levels may be slightly elevated. Such patients have been labeled as having **pseudopseudohypoparathyroidism.** Transition from normocalcemia to hypocalcemia often occurs with increasing age of the patient. These phenotypically similar but metabolically dissimilar patients may be in the same family and have the same mutations of $G_s\alpha$ protein. It is not known what other factors cause clinically overt hypocalcemia in some affected patients and not in others. There is some evidence to suggest that the $G_s\alpha$ mutation is paternally transmitted in pseudopseudohypoparathyroidism and maternally transmitted in patients with type Ia disease. The gene may be imprinted in a tissue-specific manner.

In addition to resistance to PTH, resistance to other G-protein–coupled receptors for thyroid-stimulating hormone (TSH), gonadotropins, and glucagon can result in various metabolic effects. Clinical hypothyroidism is uncommon, but basal levels of TSH are elevated

and thyrotropin-releasing hormone–stimulated TSH responses are exaggerated. Moderately decreased levels of thyroxine and increased levels of TSH have been demonstrated by newborn thyroid-screening programs, leading to the detection of type Ia PHP in infancy. In adults, gonadal dysfunction is common, as manifested by sexual immaturity, amenorrhea, oligomenorrhea, and infertility. Each of these abnormalities can be related to deficient synthesis of cAMP secondary to a deficiency of $G_s\alpha$, but it is not clear why resistance to other G-protein–dependent hormones (corticotropin, vasopressin) is much less affected.

Serum levels of calcium are low, and those of phosphorus and alkaline phosphatase are elevated. Clinical diagnosis can be confirmed by demonstration of a markedly attenuated response in urinary phosphate and cAMP after intravenous infusion of the synthetic 1-34 fragment of human PTH (teriparatide acetate). Definitive diagnosis is established by demonstration of the mutated G protein.

Type Ia with Precocious Puberty

Two boys have been reported with both type Ia PHP and gonadotropin-independent precocious puberty (see Chapter 562.7). They were found to have a temperature-sensitive mutation of the G_s protein. Thus, at normal body temperature (37°C [98.6°F]), the G_s is degraded, resulting in PHP, but in the cooler temperature of the testes (33°C [91.4°F]) the G_s mutation results in constitutive activation of the luteinizing hormone receptor and precocious puberty.

TYPE IB

Affected patients have normal levels of G protein activity and a normal phenotypic appearance. These patients have tissue-specific resistance to PTH but not to other hormones. Serum levels of calcium, phosphorus, and immunoreactive PTH are the same as those in patients with type Ia PHP. These patients also show no rise in cAMP in response to exogenous administration of PTH. Bioactive PTH is not increased. The pathophysiology of the disorder in this group of patients is caused by paternal uniparental isodisomy of chromosome 20q and resulting *GNAS1* methylation. This, along with the loss of the maternal *GNAS1* gene, leads to PTH resistance in the proximal renal tubules, which leads to impaired mineral ion homeostasis.

ACRODYSOSTOSIS WITH HORMONE RESISTANCE

Patients with acrodysostosis resemble those with PHP type Ia, but defects in the $G_s\alpha$ subunit are not present. Instead, in 1 subgroup of patients there is a defect in the gene encoding *PRKAR1A*, the cAMP-dependent regulatory subunit of protein kinase A that confers resistance to multiple hormones, including PTH. Another subgroup has a defect in a phosphodiesterase gene *Pde4d*. This subgroup also carries the phenotype of PHP type Ia but rarely exhibits the hormone resistance.

Chapter **573**

Hyperparathyroidism

Daniel A. Doyle

Excessive production of parathyroid hormone (PTH) can result from a primary defect of the parathyroid glands such as an adenoma or hyperplasia **(primary hyperparathyroidism).**

More often, the increased production of PTH is compensatory, usually aimed at correcting hypocalcemic states of diverse origins **(secondary hyperparathyroidism).** In vitamin D–deficient rickets and the malabsorption syndromes, intestinal absorption of calcium is deficient but hypocalcemia and tetany may be averted by increased activity of the parathyroid glands. In **pseudohypoparathyroidism,** PTH levels are elevated because a mutation in the $G_s\alpha$ protein interferes with response to PTH. Early in chronic renal disease, hyperphosphatemia results in a reciprocal fall in the calcium concentration with a consequent increase in PTH, but in advanced stages of renal failure, production of $1,25(OH)_2D_3$ is also decreased, leading to worsening hypocalcemia and further stimulation of PTH. In some instances, if stimulation of the parathyroid glands has been sufficiently intense and protracted, the glands continue to secrete increased levels of PTH for months or years after kidney transplantation, with resulting hypercalcemia.

ETIOLOGY

Childhood hyperparathyroidism is uncommon. Onset during childhood is usually the result of a single benign adenoma. It usually becomes manifested after 10 yr of age. There have been a number of kindreds in which multiple members have hyperparathyroidism transmitted in an autosomal dominant fashion. Most of the affected family members are adults, but children have been involved in approximately 30% of the pedigrees. Some affected patients in these families are asymptomatic, and disease is detected only by careful study. In other kindreds, hyperparathyroidism occurs as part of the constellation known as the **multiple endocrine neoplasia** (MEN) syndromes or of the hyperparathyroidism–jaw tumor syndrome.

Neonatal severe hyperparathyroidism is a rare disorder. Symptoms develop shortly after birth and consist of anorexia, irritability, lethargy, constipation, and failure to thrive. Radiographs reveal subperiosteal bone resorption, osteoporosis, and pathologic fractures. Symptoms may be mild, resolving without treatment, or can have a rapidly fatal course if diagnosis and treatment are delayed. Histologically, the parathyroid glands show diffuse hyperplasia. Affected siblings have been observed in some kindreds, and parental consanguinity has been reported in several kindreds. Most cases have occurred in kindreds with the clinical and biochemical features of **familial hypocalciuric hypercalcemia.** Infants with neonatal severe hyperparathyroidism may be homozygous or heterozygous for the mutation in the Ca^{2+}-sensing receptor gene, whereas most persons with 1 copy of this mutation exhibit autosomal dominant familial hypocalciuric hypercalcemia.

MEN type I is an autosomal dominant disorder characterized by hyperplasia or neoplasia of the endocrine pancreas (which secretes gastrin, insulin, pancreatic polypeptide, and occasionally glucagon), the anterior pituitary (which usually secretes prolactin), and the parathyroid glands. In most kindreds, hyperparathyroidism is usually the presenting manifestation, with a prevalence approaching 100% by 50 yr of age and occurring only rarely in children younger than 18 yr of age. With appropriate DNA probes, it is possible to detect carriers of the gene with 99% accuracy at birth, avoiding unnecessary biochemical screening programs.

The gene for MEN type I is on chromosome 11q13; it appears to function as a tumor-suppressor gene and follows the 2-hit hypothesis of tumor development. The first mutation (germinal) is inherited and is recessive to the dominant allele; this does not result in tumor formation. A second mutation (somatic) is required to eliminate the normal allele, which then leads to tumor formation.

Hyperparathyroidism–jaw tumor syndrome is an autosomal dominant disorder characterized by parathyroid adenomas and fibro-osseous jaw tumors. Affected patients can also have polycystic kidney disease, renal hamartomas, and Wilms tumor. Although the condition affects adults primarily, it has been diagnosed as early as age 10 yr.

MEN type II may also be associated with hyperparathyroidism (see Chapter 569.2).

Transient neonatal hyperparathyroidism has occurred in a few infants born to mothers with hypoparathyroidism (idiopathic or surgical) or with pseudohypoparathyroidism. In each case, the maternal disorder had been undiagnosed or inadequately treated during pregnancy. The cause of the condition is chronic intrauterine exposure to

hypocalcemia with resultant hyperplasia of the fetal parathyroid glands. In the newborn, manifestations involve the bones primarily, and healing occurs between 4 and 7 mo of age.

CLINICAL MANIFESTATIONS

At all ages, the clinical manifestations of hypercalcemia of any cause include muscle weakness, fatigue, headache, anorexia, abdominal pain, nausea, vomiting, constipation, polydipsia, polyuria, weight loss, and fever. When hypercalcemia is of long duration, calcium may be deposited in the renal parenchyma (nephrocalcinosis), with progressively diminished renal function. Renal calculi can develop and can cause renal colic and hematuria. Osseous changes can produce pain in the back or extremities, disturbances of gait, genu valgum, fractures, and tumors. Height can decrease from compression of vertebrae; the patient can become bedridden. Detection of completely asymptomatic patients is increasing with the advent of automated panel assays that include serum calcium determinations.

Abdominal pain is occasionally prominent and may be associated with **acute pancreatitis.** Parathyroid crisis can occur, manifested by serum calcium levels >15 mg/dL and progressive oliguria, azotemia, stupor, and coma. In infants, failure to thrive, poor feeding, and hypotonia are common.

Cognitive impairment, convulsions, and blindness can occur as sequelae of long-standing hypercalcemia. Psychiatric manifestations include depression, confusion, dementia, stupor, and psychosis.

LABORATORY FINDINGS

The serum calcium level is elevated; 39 of 45 children with adenomas had levels >12 mg/dL. The hypercalcemia is more severe in infants with parathyroid hyperplasia; concentrations ranging from 15-20 mg/dL are common, and values as high as 30 mg/dL have been reported. Even when the total serum calcium level is borderline or only slightly elevated, ionized calcium levels are often increased. The serum phosphorus level is reduced to approximately 3 mg/dL or less, and the level of serum magnesium is low. The urine can have a low and fixed specific gravity, and serum levels of nonprotein nitrogen and uric acid may be elevated. In patients with adenomas who have skeletal involvement, serum phosphatase levels are elevated, but in infants with hyperplasia the levels of alkaline phosphatase may be normal even when there is extensive involvement of bone.

Serum levels of intact PTH are elevated, especially in relation to the level of calcium. Calcitonin levels are normal. Acute hypercalcemia can stimulate calcitonin release, but with prolonged hypercalcemia, hypercalcitoninemia does not occur.

The most consistent and characteristic radiographic finding is resorption of subperiosteal bone, best seen along the margins of the phalanges of the hands. In the skull, there may be gross trabeculation or a granular appearance resulting from focal rarefaction; the lamina dura may be absent. In more advanced disease, there may be generalized rarefaction, cysts, tumors, fractures, and deformities. Approximately 10% of patients have radiographic signs of rickets. Radiographs of the abdomen can reveal renal calculi or nephrocalcinosis.

DIFFERENTIAL DIAGNOSIS

Other causes of hypercalcemia can result in a similar clinical pattern and must be differentiated from hyperparathyroidism (Table 573-1 and Fig. 573-1). A low serum phosphorus level with hypercalcemia is characteristic of primary hyperparathyroidism; elevated levels of PTH are also diagnostic. With hypercalcemia of any cause except hyperparathyroidism and familial hypocalciuric hypercalcemia, PTH levels are suppressed. Pharmacologic doses of corticosteroids lower the serum calcium level to normal in patients with hypercalcemia from other causes but generally do not affect the calcium level in patients with hyperparathyroidism.

TREATMENT

Surgical exploration is indicated in all instances. All glands should be carefully inspected; if an adenoma is discovered, it should be removed; very few instances of carcinoma are known in children. Most neonates with severe hypercalcemia require total parathyroidectomy; less-severe hypercalcemia remits spontaneously in others. Still others have been treated successfully with bisphosphonates and calcimimetics. The patient should be carefully observed postoperatively for the development of hypocalcemia and tetany; intravenous administration of calcium gluconate may be required for a few days. The serum calcium level then gradually returns to normal, and, under ordinary

circumstances, a diet high in calcium and phosphorus must be maintained for only several months after operation.

CT, real-time ultrasonography, and subtraction scintigraphy using sestamibi/technetium-pertechnetate alone and in combination have proved effective in localizing a single adenoma vs diffuse hyperplasia in 50-90% of adults. Parathyroid surgeons often rely on intraoperative selective venous sampling with intraoperative assay of PTH for localizing and removing the source of increased PTH secretion.

PROGNOSIS

The prognosis is good if the disease is recognized early and there is appropriate surgical treatment. When extensive osseous lesions are present, deformities may be permanent. A search for other affected family members is indicated.

573.1 Other Causes of Hypercalcemia

Daniel A. Doyle

FAMILIAL HYPOCALCIURIC HYPERCALCEMIA (FAMILIAL BENIGN HYPERCALCEMIA)

Patients with familial hypocalciuric hypercalcemia are usually asymptomatic, and the hypercalcemia is identified by chance during routine investigation for other conditions. The parathyroid glands are normal, PTH levels are inappropriately normal, and subtotal parathyroidectomy does not correct the hypercalcemia. Serum levels of magnesium are high normal or mildly elevated. The ratio of calcium-to-creatinine clearance is usually decreased despite hypercalcemia.

The disorder is inherited in an autosomal dominant manner and is caused by a mutant gene on chromosome 3q2. Penetrance is near 100%, and the disorder can be diagnosed early in childhood by serum and urinary calcium concentrations. Detection of other affected family members is important to avoid inappropriate parathyroid surgery. The defect is an inactivating mutation in the Ca^{2+}-sensing receptor gene. This G-protein–coupled receptor senses the level of free Ca^{2+} in the blood and triggers the pathway to increase extracellular Ca^{2+} in the face of hypocalcemia. This receptor functions in the parathyroid and kidney to regulate calcium homeostasis; inactivating mutations lead to an increased set point with respect to serum Ca^{2+}, resulting in mild to moderate hypercalcemia in heterozygotes.

GRANULOMATOUS DISEASES

Hypercalcemia occurs in 30-50% of children with sarcoidosis and less often in patients with other granulomatous diseases such as tuberculosis. Levels of PTH are suppressed, and levels of $1,25(OH)_2D_3$ are elevated. The source of **ectopic $1,25(OH)_2D_3$** is the activated macrophage, through stimulation by interferon-α from T lymphocytes, which are present in abundance in granulomatous lesions. Unlike renal tubular cells, the 1α-hydroxylase in macrophages is unresponsive to homeostatic regulation. Oral administration of prednisone (2 mg/kg/24 hr) lowers serum levels of $1,25(OH)_2D_3$ to normal and corrects the hypercalcemia.

HYPERCALCEMIA OF MALIGNANCY

Hypercalcemia often occurs in adults with a wide variety of solid tumors but is identified much less often in children. It has been reported in infants with malignant rhabdoid tumors of the kidney or congenital mesoblastic nephroma and in children with neuroblastoma, medulloblastoma, leukemia, Burkitt lymphoma, dysgerminoma, and rhabdomyosarcoma. Serum levels of PTH are rarely elevated. In most patients, the hypercalcemia associated with malignancy is caused by elevated levels of parathyroid hormone–related peptide and not PTH. Rarely, tumors produce $1,25(OH)_2D_3$ or PTH ectopically.

MISCELLANEOUS CAUSES OF HYPERCALCEMIA

Hypercalcemia can occur in infants with **subcutaneous fat necrosis.** Levels of PTH are normal. In 1 infant, the level of $1,25(OH)_2D_3$ was elevated and biopsy of the skin lesion revealed granulomatous infiltration, suggesting that the mechanism of the hypercalcemia was akin to that seen in patients with other granulomatous disease. In another infant, although the level of $1,25(OH)_2D_3$ was normal, PTH was suppressed, suggesting the hypercalcemia was not related to PTH. Treatment with prednisone is effective.

Hypophosphatasia, especially the severe infantile form, is usually associated with mild to moderate hypercalcemia (see Chapter 705). Serum levels of phosphorus are normal, and those of alkaline phosphatase are subnormal. The bones exhibit rachitic-like lesions on radiographs. Urinary levels of phosphoethanolamine, inorganic pyrophosphate, and pyridoxal 5′-phosphate are elevated; each is a natural substrate to a tissue-nonspecific (liver, bone, kidney) alkaline phosphatase enzyme. Missense mutations of the tissue-nonspecific alkaline phosphatase enzyme gene result in an inactive enzyme in this autosomal recessive disorder.

Idiopathic hypercalcemia of infancy is manifested by failure to thrive and hypercalcemia during the 1st yr of life, followed by spontaneous remission. Serum levels of phosphorus and PTH are normal. The condition has been defined as resulting from increased absorption of calcium from decreased degradation of $1,25(OH)_2D_3$. Mutations in the *CYP24A1* gene that encodes 25-hydroxyvitamin D 24-hydroxylase, the key enzyme in $1,25(OH)_2D_3$ degradation, cause excessive levels of the active vitamin D metabolite, which, in turn, causes hypercalcemia in a subset of infants who receive supplemental vitamin D. An excessive rise in the level of $1,25(OH)_2D_3$ in response to PTH administration has been reported years after the hypercalcemic phase.

Approximately 10% of patients with **Williams syndrome** also inconsistently exhibit associated infantile hypercalcemia. The phenotype consists of feeding difficulties, slow growth, elfin facies (small mandible, prominent maxilla, upturned nose), renovascular disorders, and a gregarious "cocktail party" personality. Cardiac lesions include supravalvular aortic stenosis, peripheral pulmonic stenosis, aortic hypoplasia, coronary artery stenosis, and atrial or ventricular septal defects. Nephrocalcinosis can develop if hypercalcemia persists. The IQ score of 50-70 is curiously accompanied by enhanced quantity and quality of vocabulary, auditory memory, and social use of language. A contiguous gene deletion syndrome with a submicroscopic deletion at chromosome 7q11.23, which includes deletion of 1 elastin allele, occurs in 90% of patients and seems to account for the vascular problems. Definitive diagnosis can be established by specific fluorescence in situ hybridization. The hypercalcemia and central nervous system symptoms may be caused by deletion of adjacent genes. Hypercalcemia has been successfully controlled with either prednisone or calcitonin.

Hypervitaminosis D resulting in hypercalcemia from drinking milk that has been incorrectly fortified with excessive amounts of vitamin D has been reported. Not all patients with hypervitaminosis D develop hypercalcemia. Affected infants can manifest failure to thrive, nephrolithiasis, poor renal function, and osteosclerosis. Serum levels of 25(OH)D are a better indicator of hypervitaminosis D than levels of $1,25(OH)_2D_3$ because 25(OH)D has a longer half-life.

Prolonged immobilization can lead to hypercalcemia and occasionally to decreased renal function, hypertension, and encephalopathy. Children who have hypophosphatemic rickets and undergo surgery with subsequent long-term immobilization are at risk for hypercalcemia and should therefore have their vitamin D supplementation decreased or discontinued.

Jansen-type metaphyseal chondrodysplasia is a rare genetic disorder characterized by short-limbed dwarfism and severe but asymptomatic hypercalcemia (see Chapter 704). Circulating levels of PTH and parathyroid hormone–related peptide are undetectable. These patients have an activating PTH–parathyroid hormone–related peptide receptor mutation that results in aberrant calcium homeostasis and abnormalities of the growth plate.

Section 4
Disorders of the Adrenal Gland

Chapter 574
Physiology of the Adrenal Gland

574.1 Histology and Embryology

Perrin C. White

The adrenal gland is composed of 2 endocrine tissues: the medulla and the cortex. The chromaffin cells of the adrenal medulla are derived from neuroectoderm, whereas the cells of the adrenal cortex are derived from mesoderm. Mesodermal cells also contribute to the development of the gonads. The adrenal glands and gonads have certain common enzymes involved in steroid synthesis; an inborn error in steroidogenesis in one tissue can also be present in the other.

The adrenal cortex of the older child or adult consists of 3 zones: the zona glomerulosa, the outermost zone located immediately beneath the capsule; the zona fasciculata, the middle zone; and the zona reticularis, the innermost zone, lying next to the adrenal medulla. The zona fasciculata is the largest zone, constituting approximately 75% of the cortex; the zona glomerulosa constitutes approximately 15% and the zona reticularis approximately 10%. Glomerulosa cells are small, with a lower cytoplasmic : nuclear ratio, an intermediate number of lipid inclusions, and smaller nuclei containing more condensed chromatin than the cells of the other 2 zones. The cells of the zona fasciculata are large, with a high cytoplasmic : nuclear ratio and many lipid inclusions that give the cytoplasm a foamy, vacuolated appearance. The cells are arranged in radial cords. The cells of the zona reticularis are arranged in irregular anastomosing cords. The cytoplasmic: nuclear ratio is intermediate, and the compact cytoplasm has relatively little lipid content.

The zona glomerulosa synthesizes aldosterone, the most potent natural mineralocorticoid in humans. The zona fasciculata produces cortisol, the most potent natural glucocorticoid in humans, and the zona fasciculata and zona reticularis synthesize the adrenal androgens.

The adrenal medulla consists mainly of neuroendocrine (chromaffin) cells and glial (sustentacular) cells with some connective tissue and vascular cells. Neuroendocrine cells are polyhedral, with abundant cytoplasm and small, pale-staining nuclei. Under the electron microscope, the cytoplasm contains many large secretory granules that contain catecholamines. Glial cells have less cytoplasm and more basophilic nuclei.

The primordium of the fetal adrenal gland can be recognized at 3-4 wk of gestation just cephalad to the developing mesonephros. At 5-6 wk, the gonadal ridge develops into the steroidogenic cells of the gonads and adrenal cortex; the adrenal and gonadal cells separate, the adrenal cells migrate retroperitoneally, and the gonadal cells migrate caudad. At 6-8 wk of gestation, the gland rapidly enlarges, the cells of the inner cortex differentiate to form the fetal zone, and the outer subcapsular rim remains as the definitive zone. The primordium of the adrenal cortex is invaded at this time by sympathetic neural elements that differentiate into the chromaffin cells capable of synthesizing and storing catecholamines. Catechol *O*-methyltransferase, which converts norepinephrine to epinephrine, is expressed later in gestation. By the end of the 8th wk of gestation, the encapsulated adrenal gland is associated with the upper pole of the kidney. By 8-10 wk of gestation, the cells of the fetal zone are capable of active steroidogenesis.

In the full-term infant, the combined weight of both adrenal glands is 7-9 g. At birth, the inner fetal cortex makes up approximately 80% of the gland and the outer "true" cortex, 20%. Within a few days the fetal cortex begins to involute, undergoing a 50% reduction by 1 mo of age. Conversely, the adrenal medulla is relatively small at birth and undergoes a proportionate increase in size over the 1st 6 mo after birth. By 1 yr, the adrenal glands each weigh <1 g. Adrenal growth thereafter results in adult adrenal glands reaching a combined weight of 8 g. The zonae fasciculata and glomerulosa are fully differentiated by about 3 yr of age. The zona reticularis is not fully developed until puberty.

Adrenocorticotropic hormone (ACTH) is essential for fetal adrenal growth and maturation; feedback regulation of ACTH by cortisol is apparently established by 8-10 wk of gestation. Additional factors important in fetal growth and steroidogenesis include placental chorionic gonadotropins and a number of peptide growth factors produced by the placenta and fetus.

Several transcription factors are critical for the development of the adrenal glands. The 3 transcription factors associated with adrenal hypoplasia in humans are steroidogenic factor-1 (*SF-1;* NR5A1), *DAX-1* (dosage-sensitive sex reversal, adrenal hypoplasia congenita, X chromosome; NR0B1), and the *GLI3* oncogene. Disruption of *SF-1*, encoded on chromosome 9q33, results in gonadal and often adrenal agenesis, absence of pituitary gonadotropes, and an underdeveloped ventral medial hypothalamus. In-frame deletions and frameshift and missense mutations of this gene are associated with 46,XX ovarian insufficiency and 46,XY gonadal dysgenesis. Mutations in the *DAX1* gene, encoded on Xp21, result in adrenal hypoplasia congenita and hypogonadotropic hypogonadism (see Chapter 575.1). Mutations in *GLI3* on chromosome 7p13 cause Pallister-Hall syndrome, other features of which include hypothalamic hamartoblastoma, hypopituitarism, imperforate anus, and postaxial polydactyly.

The postnatal adrenal cortex is not static but, in fact, is continually regenerated from a population of stem or progenitor cells under the adrenal capsule. These cells move radially inward (i.e., centripetally) and can differentiate into zona glomerulosa or fasciculata cells as needed in response to the appropriate trophic stimuli (see Chapter 574.3). Several signaling pathways, including sonic hedgehog and Wnt, regulate this process. Sonic hedgehog expression is restricted to the peripheral cortical cells that do not express high levels of steroidogenic genes but give rise to the underlying differentiated cells of the cortex. Wnt/β-catenin signaling maintains the undifferentiated state and adrenal fate of adrenocortical stem/progenitor cells, in part through induction of its target genes *DAX1* and inhibin-α, respectively. Adrenal tumors can result from constitutive activation of the Wnt signaling pathway (see Chapter 579), whereas mutations of *DAX1* lead to loss of the ability of the adrenal cortex to regenerate; this condition is termed *adrenal hypoplasia congenita* (see Chapter 575).

574.2 Adrenal Steroid Biosynthesis

Perrin C. White

Cholesterol is the starting substrate for all steroid biosynthesis (Fig. 574-1). Although adrenal cortex cells can synthesize cholesterol de novo from acetate, circulating plasma lipoproteins provide most of the cholesterol for adrenal cortex hormone formation. Receptors for both low-density lipoprotein and high-density lipoprotein cholesterol are expressed on the surface of adrenocortical cells; the receptor is termed scavenger receptor class B, type I. Patients with familial hypercholesterolemia who lack low-density lipoprotein receptors have unimpaired adrenal steroidogenesis, suggesting that high-density lipoprotein is the more important source of cholesterol. Cholesterol is stored as cholesteryl esters in vesicles and subsequently hydrolyzed by cholesteryl ester hydrolases to liberate free cholesterol for steroid hormone synthesis.

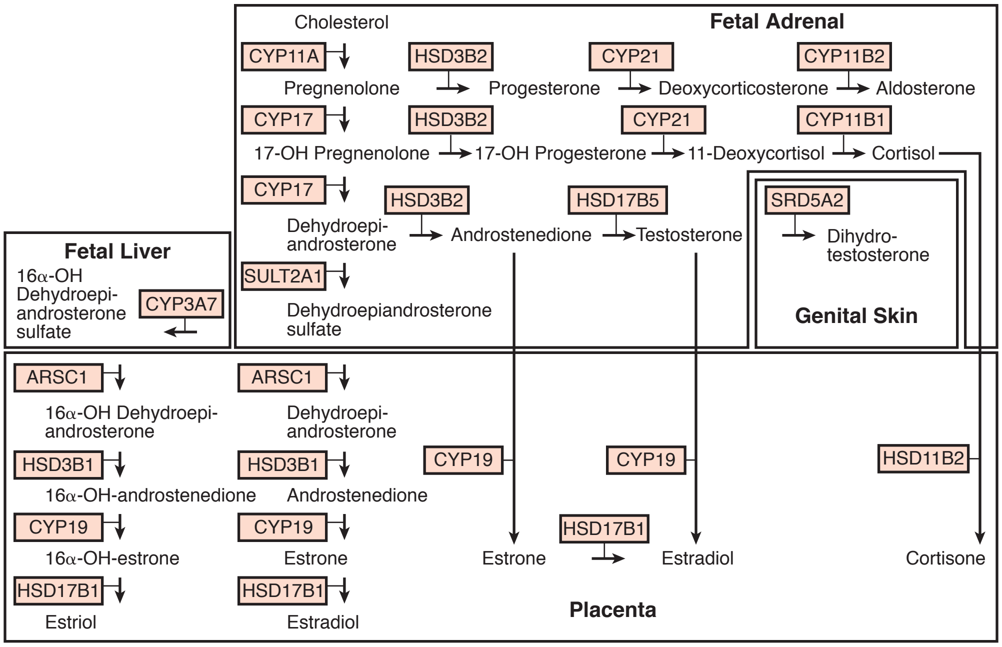

Figure 574-1 **Steroid biosynthesis and metabolism during gestation.** Conversions within the fetal adrenal cortex, fetal liver, male (i.e., testosterone-exposed) genital skin, and placenta are denoted by *arrows;* the enzyme mediating each conversion is also shown. Enzymatic conversions in the adrenal cortex are the same postnatally as prenatally, but cortisol and aldosterone biosynthesis are more prominent, and normally little testosterone is synthesized. Many of the involved enzymes are cytochromes P450 (CYPs). Adrenal enzymes include CYP 11A, cholesterol side-chain cleavage enzyme (P450scc in older terminology); HSD3B2, 3β-hydroxysteroid dehydrogenase/Δ5,Δ4 isomerase type 2; CYP 17, 17β-hydroxylase/17,20-lyase (P450c17); CYP 21, 21-hydroxylase (P450c21); CYP 11B1, 11β-hydroxylase (P450c11); CYP 11B2, aldosterone synthase (P450aldo; this enzyme mediates successive 11β-hydroxylase, 18-hydroxylase, and 18-oxidase reactions in the zona glomerulosa for the conversion of deoxycorticosterone to aldosterone). Other enzymes important in the fetoplacental unit include ARSC1, arylsulfatase; CYP 19, aromatase (P450arom); HSD3B1, 3β-hydroxysteroid dehydrogenase/Δ5,Δ4 isomerase type 1; HSD11B2, 11β-hydroxysteroid dehydrogenase type 2; HSD17B1 and HSD17B5 are 2 different 17-hydroxysteroid dehydrogenase enzymes; SRD5A2, steroid 5α-reductase type 2; SULT2A1, steroid sulfotransferase.

The rate-limiting step of adrenal steroidogenesis is importation of cholesterol across the mitochondrial outer and inner membrane. This requires several proteins, particularly the steroidogenic acute regulatory (StAR) protein. The steroidogenic acute regulatory protein has a very short half-life, and its synthesis is rapidly induced by trophic factors (corticotropin); thus, it is the main short-term (minutes to hours) regulator of steroid hormone biosynthesis.

At the mitochondrial inner membrane, the side chain of cholesterol is cleaved to yield pregnenolone. This is catalyzed by the cholesterol side-chain cleavage enzyme (cholesterol desmolase, side-chain cleavage enzyme, P450scc, CYP11A1; the last term is the current systematic nomenclature), a cytochrome P450 (CYP) enzyme. Like other P450s, this is a membrane-bound hemoprotein with a molecular mass of approximately 50 kDa. It accepts electrons from a nicotinamide adenine dinucleotide phosphate–dependent mitochondrial electron transport system consisting of 2 accessory proteins, adrenodoxin reductase (a flavoprotein) and adrenodoxin (a small protein containing nonheme iron). P450 enzymes use electrons and O_2 to hydroxylate the substrate and form H_2O. In the case of cholesterol side-chain cleavage, 3 successive oxidative reactions are performed to cleave the C20,22 carbon bond. Pregnenolone then diffuses out of mitochondria and enters the endoplasmic reticulum. The subsequent reactions that occur depend on the zone of the adrenal cortex.

ZONA GLOMERULOSA

In the zona glomerulosa, pregnenolone is converted to progesterone by 3β-hydroxysteroid dehydrogenase type 2, a nicotinamide adenine dinucleotide–positive–dependent enzyme of the short-chain dehydrogenase type. Progesterone is converted to 11-deoxycorticosterone by steroid 21-hydroxylase (P450c21, CYP21), which is another P450. Like other P450s in the endoplasmic reticulum, it uses an electron transport system with only 1 accessory protein, P450 oxidoreductase.

Deoxycorticosterone then reenters mitochondria and is converted to aldosterone by aldosterone synthase (P450aldo, CYP11B2), a P450 enzyme structurally related to cholesterol desmolase. Aldosterone synthase also carries out 3 successive oxidations: 11β-hydroxylation, 18-hydroxylation, and further oxidation of the 18-methyl carbon to an aldehyde.

ZONA FASCICULATA

In the endoplasmic reticulum of the zona fasciculata, pregnenolone and progesterone are converted by 17α-hydroxylase (P450c17, CYP17) to 17-hydroxypregenolone and 17-hydroxyprogesterone, respectively. This enzyme is not expressed in the zona glomerulosa, which consequently cannot synthesize 17-hydroxylated steroids. 17-Hydroxypregnenolone is converted to 17-hydroxyprogesterone and 11-deoxycortisol by the same 3β-hydroxysteroid and 21-hydroxylase enzymes, respectively, as are active in the zona glomerulosa. Thus, inherited disorders in these enzymes affect both aldosterone and cortisol synthesis (see Chapter 576). Finally, 11-deoxycortisol reenters mitochondria and is converted to cortisol by steroid 11β-hydroxylase (P450c11, CYP11B1). This enzyme is closely related to aldosterone synthase but has low 18-hydroxylase and nonexistent 18-oxidase activity. Thus, under normal circumstances the zona fasciculata cannot synthesize aldosterone.

ZONA RETICULARIS

In the zona reticularis and to some extent in the zona fasciculata, the 17-hydroxylase (CYP17) enzyme has an additional activity, cleavage of the 17,20 carbon–carbon bond. This converts 17-hydroxypregnenolone to dehydroepiandrosterone (DHEA). DHEA is converted to androstenedione by HSD3B. This may be further converted in other tissues to testosterone and estrogens.

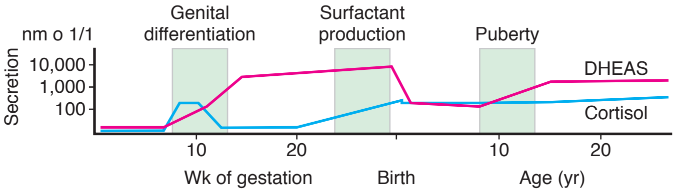

Figure 574-2 Relative levels of cortisol and dehydroepiandrosterone sulfate (DHEAS) secretion by the fetal adrenal cortex during gestation as well as postnatally. Approximate times of several events are shown. Vertical axis is logarithmic, but values are approximate. Horizontal axis is not to scale.

FETOPLACENTAL UNIT

Steroid synthesis in the fetal adrenal varies during gestation (see Figs. 574-1 and 574-2). Shortly after the fetal adrenal gland forms (wk 8-10), it efficiently secretes cortisol, which is able to negatively feedback on the fetal pituitary and hypothalamus to suppress ACTH secretion. This is critical time for differentiation of the external genitalia in both sexes (see Chapter 576.1); to prevent virilization, the female fetus must not be exposed to high levels of androgens of adrenal origin, and placental aromatase activity must remain low during this time to minimize conversion of testosterone to estradiol in male fetuses, which would interfere with masculinization. After wk 12, HSD3B activity in the fetal adrenal gland decreases and steroid sulfokinase activity increases. Thus, the major steroid products of the midgestation fetal adrenal gland are DHEA and DHEA sulfate (DHEAS) and, by 16α-hydroxylation in the liver, 16α-hydroxy DHEAS. Aromatase activity increases in the placenta at the same time, and steroid sulfatase activity is high as well. Thus, the placenta uses DHEA and DHEAS as substrates for estrone and estradiol and 16α-OH DHEAS as a substrate for estriol. Cortisol activity is low during the 2nd trimester, which might serve to prevent premature secretion of surfactant by the developing fetal lungs; surfactant levels can affect the timing of parturition. As term approaches, fetal cortisol concentration increases as a result of increased cortisol secretion and decreased conversion of cortisol to cortisone by 11β-hydroxysteroid dehydrogenase type 2 (HSD11B2). Low levels of aldosterone are produced in mid-gestation, but aldosterone secretory capacity increases near term.

Bibliography is available at Expert Consult.

574.3 Regulation of the Adrenal Cortex

Perrin C. White

REGULATION OF CORTISOL SECRETION

Glucocorticoid secretion is regulated mainly by ACTH (corticotropin), a 39-amino-acid peptide that is produced in the anterior pituitary. It is synthesized as part of a larger-molecular-weight precursor peptide known as proopiomelanocortin. This precursor peptide is also the source of β-lipotropin. ACTH and β-lipotropin are cleaved further to yield α- and β-melanocyte–stimulating hormone, corticotropin-like intermediate lobe peptide, γ-lipotropin, β- and γ-endorphin, and enkephalin (see Chapter 556).

ACTH is released in secretory bursts of varying amplitude throughout the day and night. The normal diurnal rhythm of cortisol secretion is caused by the varying amplitudes of ACTH pulses. Pulses of ACTH and cortisol occur every 30-120 min, are highest at about the time of waking, are low in late afternoon and evening, and reach their lowest point 1 or 2 hr after sleep begins.

Corticotropin-releasing hormone (CRH), synthesized by neurons of the parvicellular division of the hypothalamic paraventricular nucleus, is the most important stimulator of ACTH secretion. Arginine vasopressin (AVP) augments CRH action. Neural stimuli from the brain cause the release of CRH and AVP (see Chapter 556). AVP and CRH are secreted in the hypophyseal-portal circulation in a pulsatile manner. This pulsatile secretion appears to be responsible for the pulsatile (ultradian) release of ACTH. The circadian rhythm of corticotropin release is probably induced by a corresponding circadian rhythm of hypothalamic CRH secretion, regulated by the suprachiasmatic nucleus with input from other areas of the brain. Cortisol exerts a negative feedback effect on the synthesis and secretion of ACTH, CRH, and AVP. ACTH inhibits its own secretion, a feedback effect mediated at the level of the hypothalamus. Thus the secretion of cortisol is a result of the interaction of the hypothalamus, pituitary, and adrenal glands and other neural stimuli.

ACTH acts through a specific G-protein–coupled receptor (also termed melanocortin receptor-2, encoded by the *MCR2* gene) to activate adenylate cyclase and increase levels of cyclic adenosine monophosphate. Cyclic adenosine monophosphate has short-term (minutes to hours) effects on cholesterol transport into mitochondria by increasing expression of steroidogenic acute regulatory protein. The long-term effects (hours to days) of ACTH stimulation are to increase the uptake of cholesterol and the expression of genes encoding the enzymes required to synthesize cortisol. These transcriptional effects occur at least in part through increased activity of protein kinase A, which phosphorylates several transcriptional regulatory factors. MC2R trafficking and signaling are dependent on the MC2R accessory protein (MRAP). Mutations in either MC2R or MRAP can cause familial glucocorticoid deficiency (see Chapter 575).

REGULATION OF ALDOSTERONE SECRETION

The rate of aldosterone synthesis, which is normally 100- to 1,000-fold less than that of cortisol synthesis, is regulated mainly by the renin–angiotensin system and by potassium levels, with ACTH having only a short-term effect. In response to decreased intravascular volume, renin is secreted by the juxtaglomerular apparatus of the kidney. Renin is a proteolytic enzyme that cleaves angiotensinogen (renin substrate), an α_2-globulin produced by the liver, to yield the inactive decapeptide angiotensin I. Angiotensin-converting enzyme in the lungs and other tissues rapidly cleaves angiotensin I to the biologically active octapeptide angiotensin II. Cleavage of angiotensin II produces the heptapeptide angiotensin III. Angiotensins II and III are potent stimulators of aldosterone secretion; angiotensin II is a more potent vasopressor agent. Angiotensins II and III occupy a G-protein–coupled receptor activating phospholipase C. This protein hydrolyzes phosphatidylinositol bisphosphate to produce inositol triphosphate and diacylglycerol, which raise intracellular calcium levels and activate protein kinase C and calmodulin-activated kinases. Similarly, increased levels of extracellular potassium depolarize the cell membrane and increase calcium influx through voltage-gated L-type calcium channels. Phosphorylation of transcriptional regulatory factors by calmodulin-activated kinases increases transcription of the aldosterone synthase (CYP11B2) enzyme required for aldosterone synthesis.

REGULATION OF ADRENAL ANDROGEN SECRETION

The mechanisms by which the adrenal androgens DHEA and androstenedione are regulated are not completely understood. Adrenarche is a maturational process in the adrenal gland that results in increased adrenal androgen secretion between the ages of 5 and 20 yr. The process begins before the earliest signs of puberty and continues throughout the years when puberty is occurring. Histologically, it is associated with the appearance of the zona reticularis. Whereas ACTH stimulates adrenal androgen production acutely and clearly is the primary stimulus for cortisol release, additional factors have been implicated in the stimulation of the adrenal androgens. These include a relative decrease in expression of HSD3B in the zona reticularis and possibly increases in 17,20-lyase activity owing to phosphorylation of CYP17 or increased cytochrome b5 expression.

574.4 Adrenal Steroid Hormone Actions

Perrin C. White

Steroid hormones act through several distinct receptors corresponding to the known biologic activities of the steroid hormones: glucocorticoid, mineralocorticoid, progestin, estrogen, and androgen. These receptors belong to a larger superfamily of nuclear transcriptional factors that include, among others, thyroid hormone and retinoic acid receptors. They have a common structure that includes a carboxyterminal ligand-binding domain and a midregion DNA-binding domain. The latter domain contains 2 zinc fingers, each of which consists of a loop of amino acids stabilized by 4 cysteine residues chelating a zinc ion.

Unliganded glucocorticoid and mineralocorticoid receptors are found mainly in the cytosol. Hormone molecules diffuse through the cell membrane and bind receptors, changing their conformation and causing them to be translocated to the nucleus, where they bind DNA at specific hormone-response elements. Bound receptors can recruit other transcriptional coregulatory factors to DNA.

Whereas different steroids can share bioactivities because of their ability to bind to the same receptor, a given steroid can exert diverse biologic effects in different tissues. The diversity of hormonal responses is determined by the different genes that are regulated by each hormone in different tissues. Additionally, different combinations of coregulators are expressed in different tissues, allowing each steroid hormone to have many different effects. Moreover, enzymes can increase or decrease the affinity of steroids for their receptors and thus modulate their activity. 11β-Hydroxysteroid dehydrogenase type 1 (HSD11B1) converts cortisone, which is not a ligand for the glucocorticoid receptor, to cortisol, which is an active glucocorticoid. This increases local glucocorticoid concentrations in several tissues, especially the liver, where glucocorticoids maintain hepatic glucose output (see Chapter 575.4). Overexpression of this enzyme in adipose tissue can predispose to development of obesity. Conversely, HSD11B2 oxidizes cortisol to cortisone, particularly in the kidney, preventing mineralocorticoid receptors from being occupied by high levels of cortisol (see Chapter 575.4).

Although corticosteroid receptors mainly act in the nucleus, some responses to both glucocorticoids and mineralocorticoids begin within minutes, an interval too short to be accounted for by increased gene transcription and protein synthesis. Such "nongenomic" effects can in some cases be mediated by cell membrane–associated isoforms of the classic glucocorticoid and mineralocorticoid receptors, which can couple to a variety of rapid intracellular signaling pathways such as G proteins. Direct interactions with other proteins, such as ion channels, have been documented as well, particularly in the nervous system.

ACTIONS OF GLUCOCORTICOIDS

Glucocorticoids are essential for survival. The term *glucocorticoid* refers to the glucose-regulating properties of these hormones. However, glucocorticoids have multiple effects on carbohydrate, lipid, and protein metabolism. They also regulate immune, circulatory, and renal function. They influence growth, development, bone metabolism, and central nervous system activity.

In stress situations, glucocorticoid secretion can increase up to 10-fold. This increase is believed to enhance survival through increased cardiac contractility, cardiac output, sensitivity to the pressor effects of catecholamines and other pressor hormones, work capacity of the skeletal muscles, and capacity to mobilize energy stores.

Metabolic Effects

The primary action of the glucocorticoids on carbohydrate metabolism is to increase glucose production by increasing hepatic gluconeogenesis. Glucocorticoids also increase cellular resistance to insulin, thereby decreasing entry of glucose into the cell. This inhibition of glucose uptake occurs in adipocytes, muscle cells, and fibroblasts. In addition to opposing insulin action, glucocorticoids can work in parallel with insulin to protect against long-term starvation by stimulating glycogen deposition and production in liver. Both hormones stimulate glycogen synthetase activity and decrease glycogen breakdown. Glucocorticoid excess can cause hyperglycemia, and glucocorticoid deficiency can cause hypoglycemia.

Glucocorticoids increase free fatty acid levels by enhancing lipolysis, decreasing cellular glucose uptake, and decreasing glycerol production, which is necessary for reesterification of fatty acids. This increase in lipolysis is also stimulated through the permissive enhancement of lipolytic action of other factors such as epinephrine. This action affects adipocytes differently according to their anatomic locations. In the patient with glucocorticoid excess, fat is lost in the extremities but it is increased in the trunk (centripetal obesity), neck, and face (moon facies). This may involve effects on adipocyte differentiation.

Glucocorticoids generally exert a catabolic or antianabolic effect on protein metabolism. Proteolysis in fat, skeletal muscle, bone, lymphoid, and connective tissue increases amino acid substrates that can be used in gluconeogenesis. Cardiac muscle and the diaphragm are almost entirely spared from this catabolic effect.

Circulatory and Renal Effects

Glucocorticoids have a positive inotropic influence on the heart, increasing the left ventricular work index. Moreover, they have a permissive effect on the actions of epinephrine and norepinephrine on both the heart and the blood vessels. In the absence of glucocorticoids, decreased cardiac output and shock can develop; in states of glucocorticoid excess, hypertension is often observed. This may be a result of activation of the mineralocorticoid receptor (see Chapter 575.4), which occurs when renal HSD11B is saturated by excessive levels of glucocorticoids.

Growth

In excess, glucocorticoids inhibit linear growth and skeletal maturation in children, apparently through direct effects on the epiphyses. However, glucocorticoids are also necessary for normal growth and development. In the fetus and neonate, they accelerate the differentiation and development of various tissues, including the hepatic and gastrointestinal systems, as well as the production of surfactant in the fetal lung. Glucocorticoids are often given to pregnant women at risk for delivery of premature infants in an effort to accelerate these maturational processes (see Chapters 97.2 and 101.3).

Immunologic Effects

Glucocorticoids play a major role in immune regulation. They inhibit synthesis of glycolipids and prostaglandin precursors and the actions of bradykinin. They also block secretion and actions of histamine and proinflammatory cytokines (tumor necrosis factor-α, interleukin-1, and interleukin-6), thus diminishing inflammation. High doses of glucocorticoids deplete monocytes, eosinophils, and lymphocytes, especially T cells. They do so at least in part by inducing cell-cycle arrest in the G_1 phase and by activating apoptosis through glucocorticoid receptor–mediated effects. The effects on lymphocytes are primarily exerted on T-helper 1 cells and hence on cellular immunity, whereas the T-helper 2 cells are spared, leading to a predominantly humoral immune response. Pharmacologic doses of glucocorticoids can also decrease the size of immunologic tissues (spleen, thymus, and lymph nodes).

Glucocorticoids increase circulating polymorphonuclear cell counts, mostly by preventing their egress from the circulation. Glucocorticoids decrease diapedesis, chemotaxis, and phagocytosis of polymorphonuclear cells. Thus, the mobility of these cells is altered such that they do not arrive at the site of inflammation to mount an appropriate immune response. High levels of glucocorticoids decrease inflammatory and cellular immune responses and increase susceptibility to certain bacterial, viral, fungal, and parasitic infections.

Effects on Skin, Bone, and Calcium

Glucocorticoids inhibit fibroblasts, leading to increased bruising and poor wound healing through cutaneous atrophy. This effect explains

the thinning of the skin and striae that are seen in patients with Cushing syndrome.

Glucocorticoids have the overall effect of decreasing serum calcium and have been used in emergency therapy for certain types of hypercalcemia. This hypocalcemic effect probably results from a decrease in the intestinal absorption of calcium and a decrease in the renal reabsorption of calcium and phosphorus. Serum calcium levels, however, generally do not fall below normal because of a secondary increase in parathyroid hormone secretion.

The most significant effect of long-term glucocorticoid excess on calcium and bone metabolism is **osteoporosis.** Glucocorticoids inhibit osteoblastic activity by decreasing the number and activity of osteoblasts. Glucocorticoids also decrease osteoclastic activity but to a lesser extent, leading to low bone turnover with an overall negative balance. The tendency of glucocorticoids to lower serum calcium and phosphate levels causes secondary hyperparathyroidism. These actions decrease bone accretion and cause a net loss of bone mineral. Compliance with oral bisphosphonates, agents that are effective against glucocorticoid-induced osteoporosis, is poor, but evidence suggests that yearly treatment with intravenous zoledronic acid is just as effective.

Central Nervous System Effects

Glucocorticoids readily penetrate the blood–brain barrier and have direct effects on brain metabolism. They decrease certain types of central nervous system edema and are often used to treat increased intracranial pressure. They stimulate appetite and cause insomnia with a reduction in rapid eye movement sleep. There is an increase in irritability and emotional lability, with an impairment of memory and ability to concentrate. Mild to moderate glucocorticoid excess for a limited period often causes a feeling of euphoria or well-being, but glucocorticoid excess and deficiency can both be associated with clinical depression. Glucocorticoid excess produces **psychosis** in some patients.

Glucocorticoid effects in the brain are mediated largely through interactions with both the mineralocorticoid and glucocorticoid receptors (sometimes referred to in this context as type I and type II corticosteroid receptors, respectively). Activation of type II receptors increases sensitivity of hippocampal neurons to the neurotransmitter serotonin, which might help explain the euphoria associated with high doses of glucocorticoids. Glucocorticoids suppress release of CRH in the anterior hypothalamus, but they stimulate it in the central nucleus of the amygdala and lateral bed nucleus of the stria terminalis, where it can mediate fear and anxiety states. Glucocorticoids and other steroids might have nongenomic effects by modulating activities of both γ-aminobutyric acid and *N*-methyl-D-aspartate receptors.

ACTIONS OF MINERALOCORTICOIDS

The most important mineralocorticoids are aldosterone and, to a lesser degree, 11-deoxycorticosterone; corticosterone and cortisol are normally not important as mineralocorticoids unless secreted in excess. Mineralocorticoids have more limited actions than glucocorticoids. Their major function is to maintain intravascular volume by conserving sodium and eliminating potassium and hydrogen ions. They exert these actions in the kidney, gut, and salivary and sweat glands. Aldosterone can have distinct effects in other tissues. Mineralocorticoid receptors are found in the heart and vascular endothelium, and aldosterone increases myocardial fibrosis in heart failure.

Mineralocorticoids have their most important actions in the distal convoluted tubules and cortical collecting ducts of the kidney, where they induce reabsorption of sodium and secretion of potassium. In the medullary collecting duct, they act in a permissive fashion to allow vasopressin to increase osmotic water flux. Thus, patients with mineralocorticoid deficiency can develop weight loss, hypotension, hyponatremia, and hyperkalemia, whereas patients with mineralocorticoid excess can develop hypertension, hypokalemia, and metabolic alkalosis (see Chapters 575-578).

The mechanisms by which aldosterone affects sodium excretion are incompletely understood. Most effects of aldosterone are presumably due to changes in gene expression mediated by the mineralocorticoid receptor, and indeed levels of subunits of both the Na^+,K^+-adenosine triphosphatase and the epithelial sodium channel increase in response to aldosterone. Additionally, aldosterone increases expression of the serum and glucocorticoid-regulated kinase, which indirectly reduces turnover of epithelial sodium channel subunits and thus increases the number of open sodium channels.

The mineralocorticoid receptor has similar affinities in vitro for cortisol and aldosterone, yet cortisol is a weak mineralocorticoid in vivo. This discrepancy results from the action of HSD11B2, which converts cortisol to cortisone. Cortisone is not a ligand for the receptor, whereas aldosterone is not a substrate for the enzyme. Pharmacologic inhibition (as occurs with excessive consumption of licorice) or genetic deficiency of this enzyme allows cortisol to occupy renal mineralocorticoid receptors and produce sodium retention and hypertension; the genetic condition is termed *apparent mineralocorticoid excess syndrome*.

ACTIONS OF THE ADRENAL ANDROGENS

Many actions of adrenal androgens are exerted through their conversion to active androgens or estrogens such as testosterone, dihydrotestosterone, estrone, and estradiol. In men, <2% of the biologically important androgens are derived from adrenal production, whereas in women approximately 50% of androgens are of adrenal origin. The adrenal contribution to circulating estrogen levels is mainly important in pathologic conditions such as feminizing adrenal tumors. Adrenal androgens contribute to the physiologic development of pubic and axillary hair during normal puberty. They also play an important role in the pathophysiology of congenital adrenal hyperplasia, premature adrenarche, adrenal tumors, and Cushing syndrome (see Chapters 576, 577, and 579).

In humans, circulating levels of DHEA and DHEAS, the chief adrenal androgens, reach a peak in early adulthood and then decline. This has led to speculation that age-related physiologic changes might be reversed by DHEA administration, and beneficial effects have been suggested (but not proved) on insulin sensitivity, bone mineral density, muscle mass, cardiovascular risk, obesity, cancer risk, autoimmunity, and the central nervous system.

Synthetic Corticosteroids

Many synthetic analogs of cortisone and hydrocortisone are available. Prednisone and prednisolone are derivatives with an additional double bond in ring A. Like cortisone, prednisone is not an active steroid but it is converted to prednisolone by HSD11B1 in the liver. Prednisone and prednisolone are 4-5 times as potent in antiinflammatory and carbohydrate activity but have slightly less effect on retention of water and sodium than cortisol. Halogenated derivatives have different effects. Betamethasone and dexamethasone have 25-40 times the glucocorticoid potency of cortisol but have little mineralocorticoid effect. These analogs are usually used in pharmacologic doses for their antiinflammatory or immunosuppressive properties. The antiinflammatory activity of fludrocortisone is about 15 times that of hydrocortisone, but fludrocortisone is more than 125 times as active a mineralocorticoid; it is used to treat aldosterone deficiency.

574.5 Adrenal Medulla

Perrin C. White

The principal hormones of the adrenal medulla are the physiologically active catecholamines: dopamine, norepinephrine, and epinephrine (Fig. 574-3). Catecholamine synthesis also occurs in the brain, in sympathetic nerve endings, and in chromaffin tissue outside the adrenal medulla. Metabolites of catecholamines are excreted in the urine, principally 3-methoxy-4-hydroxymandelic acid, metanephrine,

and normetanephrine. Urinary metanephrines and catecholamines are measured to detect pheochromocytomas of the adrenal medulla and sympathetic nervous system (see Chapter 580).

The proportions of epinephrine and norepinephrine in the adrenal gland vary with age. In early fetal stages, there is practically no epinephrine; at birth, norepinephrine remains predominant. However in adults, norepinephrine accounts for only 10-30% of the pressor amines in the medulla.

The effects of catecholamines are mediated through a series of G-protein–coupled adrenergic receptors. Both epinephrine and norepinephrine raise the mean arterial blood pressure, but only epinephrine increases cardiac output. By increasing peripheral vascular resistance, norepinephrine increases systolic and diastolic blood pressures with only a slight reduction in the pulse rate. Epinephrine increases the pulse rate and, by decreasing the peripheral vascular resistance, decreases the diastolic pressure. The hyperglycemic and calorigenic effects of norepinephrine are much less pronounced than are those of epinephrine.

Chapter 575

Adrenocortical Insufficiency

Perrin C. White

In primary adrenal insufficiency, congenital or acquired lesions of the adrenal cortex prevent production of cortisol and often aldosterone (Table 575-1). Acquired primary adrenal insufficiency is termed *Addison disease*. Dysfunction of the anterior pituitary gland or hypothalamus can cause a deficiency of corticotropin (adrenocorticotropic hormone [ACTH]) and lead to hypofunction of the adrenal cortex, termed *secondary adrenal insufficiency;* the term *tertiary adrenal insufficiency* is sometimes used to denote cases arising from hypothalamic dysfunction (Table 575-2).

Table 575-1 Causes of Primary Adrenal Insufficiency

	PATHOGENESIS OR GENETICS	CLINICAL FEATURES IN ADDITION TO ADRENAL INSUFFICIENCY
CONGENITAL ADRENAL HYPERPLASIA		
21-Hydroxylase deficiency	*CYP21A2* mutations	Hyperandrogenism
11β-Hydroxylase deficiency	*CYP11B1* mutations	Hyperandrogenism, hypertension
3β-Hydroxysteroid dehydrogenase type 2 deficiency	*HSD3B2* mutations	Ambiguous genitalia in boys, postnatal virilization in girls
17α-Hydroxylase deficiency	*CYP17A1* mutations	XY sex reversal, pubertal delay in both sexes, hypertension
P450 oxidoreductase deficiency	*POR* mutations	Skeletal malformation (Antley-Bixler syndrome), abnormal genitalia
P450 side-chain cleavage deficiency	*CYP11A1* mutations	XY sex reversal
Congenital lipoid adrenal hyperplasia	*STAR* mutations	XY sex reversal
OTHER GENETIC DISORDERS		
Adrenoleukodystrophy or adrenomyeloneuropathy	*ABCD1* mutations	Weakness, spasticity, dementia, blindness, quadriparesis. Adrenomyeloneuropathy is a milder variant of adrenoleukodystrophy with slower progression
Triple A syndrome (Allgrove syndrome)	*AAAS* mutations	Achalasia, alacrima, cognitive deficits, neuromuscular deficits, hyperkeratosis
Smith-Lemli-Opitz syndrome	*DHCR7* mutations	Craniofacial malformations, developmental delay growth failure, cholesterol deficiency
Wolman disease	*LIPA* mutations	Bilateral adrenal calcification, hepatosplenomegaly
Kearns-Sayre syndrome	Mitochondrial DNA deletions	External ophthalmoplegia, retinal degeneration, cardiac conduction defects, other endocrine disorders
Pallister-Hall syndrome	*GLI3* mutations	hypothalamic hamartoblastoma, hypopituitarism, imperforate anus, and postaxial polydactyly
IMAGe syndrome	*CDKN1C* mutations	Intrauterine growth retardation, metaphyseal dysplasia, genital abnormalities
Adrenal Hypoplasia Congenita		
X-linked	*NR0B1* mutations	Hypogonadotropic hypogonadism in boys
Xp21 contiguous gene syndrome	Deletion of genes for Duchenne muscular dystrophy, glycerol kinase, and *NR0B1*	Duchenne muscular dystrophy, glycerol kinase deficiency, psychomotor retardation
SF-1 linked	*NR5A1* mutations	XY sex reversal
Familial Glucocorticoid Deficiency or Corticotropin Insensitivity Syndromes		
Type 1	*MC2R* mutations	Tall stature, characteristic facial features, such as hypertelorism and frontal bossing
Type 2	*MRAP* mutations	
Variant of familial glucocorticoid deficiency	*MCM4* mutations	Growth failure, increased chromosomal breakage, natural killer cell deficiency
Variant of familial glucocorticoid deficiency	*NNT* mutations	
AUTOIMMUNE		
Isolated	Sporadic; associations with *HLA-DR3-DQ2, HLA-DR4-DQ8, MICA, CTLA4, PTPN22, CIITA, CLEC16A*	None
APS type 1 (APECED)	*AIRE* mutations	Chronic mucocutaneous candidosis, hypoparathyroidism, other autoimmune diseases
APS type 2	Sporadic; associations with *HLA-DR3, HLA-DR4, CTLA4*	Thyroid autoimmune disease, type 1 diabetes, other autoimmune diseases
APS type 4	Sporadic; associations with *HLA-DR3, CTLA4*	Other autoimmune diseases (autoimmune gastritis, vitiligo, coeliac disease, alopecia), excluding thyroid disease and type 1 diabetes
INFECTIOUS		
Tuberculous adrenalitis	Tuberculosis	Tuberculosis-associated manifestations in other organs
AIDS	HIV-1	Other AIDS-associated diseases
Fungal adrenalitis	Histoplasmosis, cryptococcosis, coccidioidomycosis	Opportunistic infections
Meningococcal sepsis (Waterhouse-Friderichsen syndrome),	*Neisseria meningitidis*	
African trypanosomiasis	*Trypanosoma brucei*	Other trypanosomiasis-associated organ involvement
OTHER ACQUIRED CAUSES		
Bilateral adrenal hemorrhage	Meningococcal sepsis (Waterhouse-Friderichsen syndrome), primary antiphospholipid syndrome, traumatic birth, anticoagulation	Symptoms and signs of underlying disease
Bilateral adrenal metastases	Mainly cancers of the lung, stomach, breast, and colon	Symptoms and signs of underlying disease
Bilateral adrenal infiltration	Primary adrenal lymphoma, amyloidosis, hemochromatosis, sarcoidosis (rare)	Symptoms and signs of underlying disease
Bilateral adrenalectomy		Symptoms and signs of underlying disease

Table 575-1 Causes of Primary Adrenal Insufficiency—cont'd

	PATHOGENESIS OR GENETICS	CLINICAL FEATURES IN ADDITION TO ADRENAL INSUFFICIENCY
DRUG-INDUCED		
Mitotane (o,p-DDD)	Cytotoxicity	None, unless related to drug
Aminoglutethimide	Inhibition of cholesterol side chain cleavage enzyme (CYP11A1)	None, unless related to drug
Trilostane	Inhibition of 3β-hydroxysteroid dehydrogenase type 2	None, unless related to drug
Etomidate	Inhibition of 11β-hydroxylase (CYP11B1)	None, unless related to drug
Ketoconazole, fluconazole	Inhibition of mitochondrial cytochrome P450 enzymes (e.g., CYP11A1, CYP11B1)	None, unless related to drug

AAAS, achalasia, adrenocortical insufficiency, alacrima syndrome; ABCD, ATP-binding cassette, subfamily D; ABCG5, ATP-binding cassette, subfamily G, member 5; ABCG8, ATP-binding cassette, subfamily G, member 8; APECED, autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy; APS, autoimmune polyendocrinopathy syndrome; CIITA, class II transactivator; CTLA-4, cytotoxic T-lymphocyte antigen 4; DHCR7, 7-dehydrocholesterol reductase; HLA, human leukocyte antigen; IMAGe, *i*ntrauterine growth restriction (IUGR), *m*etaphyseal dysplasia, *a*drenal hypoplasia congenita (AHC), and *g*enitourinary abnormalities; LIPA, lipase A; MC2R, melanocortin 2 receptor; MCM4, minichromosome maintenance complex component 4; MICA, major histocompatibility complex class I chain-related gene A; MRAP, melanocortin 2 receptor accessory protein; PTPN22, protein tyrosine phosphatase, non-receptor type 22; StAR, steroidogenic acute regulatory protein.

Table 575-2 Causes of Secondary Adrenal Insufficiency

	ETIOLOGIES	CLINICAL MANIFESTATIONS IN ADDITION TO ADRENAL INSUFFICIENCY
DRUG-INDUCED		
Abrupt cessation of glucocorticoid therapy (systemic or topical)	Suppression of CRH and ACTH secretion leading to atrophy of the adrenal cortex	Primary disease-associated symptoms
OTHER ACQUIRED CAUSES		
Hypothalamic or pituitary tumors	Adenomas, cysts, craniopharyngiomas, ependymomas, meningiomas, rarely carcinomas, metastasis	Panhypopituitarism*; primary disease-associated symptoms
Traumatic brain injury		Panhypopituitarism*; primary disease-associated symptoms
Hypothalamic or pituitary surgery or irradiation		Panhypopituitarism*; primary disease-associated symptoms
Infections or infiltrative processes	Lymphocytic hypophysitis, hemochromatosis, tuberculosis, meningitis, sarcoidosis, actinomycosis, histiocytosis X, Wegener granulomatosis	Panhypopituitarism*; primary disease-associated symptoms
Pituitary apoplexy (when occurring in a peripartum mother, termed Sheehan syndrome)	High blood loss or hypotension	Abrupt onset of severe headache, visual disturbance, nausea, vomiting; panhypopituitarism*; primary disease-associated symptoms
CONGENITAL OR GENETIC CAUSES		
Abnormal Central Nervous System Development		
Anencephaly	Multiple	Primary disease-associated symptoms
Holoprosencephaly	Multiple	Primary disease-associated symptoms
Combined Pituitary Hormone Deficiency (CPHD)†		
CPHD2	Mutations in *PROP1* (paired-like homeobox 1)	Panhypopituitarism; corticotropin deficiency occurs in adolescence
CPHD3	Mutations in *LHX3* (LIM homeobox 3)	Panhypopituitarism; deafness, short neck
CPHD4	Mutations in *LHX4* (LIM homeobox 4)	Panhypopituitarism; small sella, cerebellar defects
Septooptic dysplasia, CPHD5	Mutations in *HESX1* (HESX homeobox 1)	Panhypopituitarism; septooptic dysplasia (blindness owing to hypoplasic optic nerves, absence of the septum pellucidum); developmental delay
CPHD6	Mutations in *OTX2* (orthodenticle homeobox 2)	Panhypopituitarism; ectopic posterior pituitary gland
X-linked panhypopituitarism	Mutations in *SOX3* (SRY(sex-determining region Y) box 3)	Panhypopituitarism; infundibular hypoplasia, developmental delay
Other Genetic Syndromes Affecting Corticotropin Secretion		
Congenital proopiomelanocortin deficiency	Mutations in *POMC* (proopiomelanocortin)	Early-onset severe obesity, hyperphagia, red hair
Prohormone convertase 1/3 deficiency	Mutations in *PC1* (prohormone convertase 1/3)	Obesity, malabsorption or diarrhea, hypogonadotropic hypogonadism
Isolated ACTH (corticotropin) deficiency	Mutations in *TBX19* (T-box 19)	
Prader-Willi syndrome	Deletion or silencing of genes on the parental copy of genes within the imprinted chromosome region 15q11-q13 including *SNRPN* (small nuclear ribonucleoprotein polypeptide N) and *NDN* (necdin, melanoma antigen (MAGE) family member)	Dysmorphic features, hypotonia, developmental delay, obesity, growth hormone deficiency, hypogonadotropic hypogonadism

*The associated anterior and/or posterior hormone deficiencies may vary.

†CPHD1 (mutations in *POUF1*) is not associated with corticotropin deficiency.

575.1 Primary Adrenal Insufficiency

Perrin C. White

Primary adrenal insufficiency in children is most frequently caused by genetic conditions that are often but not always manifested in infancy and less often by acquired problems such as autoimmune conditions (Table 575-3). Susceptibility to autoimmune conditions often has a genetic basis, and so these distinctions are not absolute.

INHERITED ETIOLOGIES

Inborn Defects of Steroidogenesis

The most common causes of adrenocortical insufficiency in infancy are the salt-losing forms of congenital adrenal hyperplasia (see Chapter 576). Approximately 75% of infants with 21-hydroxylase deficiency, almost all infants with lipoid adrenal hyperplasia, and most infants with a deficiency of 3β-hydroxysteroid dehydrogenase manifest salt-losing symptoms in the newborn period because they are unable to synthesize either cortisol or aldosterone.

Adrenal Hypoplasia Congenita

Adrenal hypoplasia congenita (AHC) is a relatively frequent cause of adrenal failure in boys along with congenital adrenal hyperplasia, autoimmune disease, and adrenoleukodystrophy. The name of the disorder notwithstanding, AHC is predominantly a failure of development of the definitive zone of the adrenal cortex; the fetal zone may be relatively normal. Consequently, adrenal insufficiency generally becomes evident as the fetal zone involutes postnatally (see Chapter 574), with onset in infancy or in the 1st 2 yr of life, but occasionally in later childhood or even adulthood. In some cases, aldosterone deficiency becomes evident before cortisol deficiency.

The disorder is caused by mutation of the *DAX1 (NR0B1)* gene, a member of the nuclear hormone receptor family, located on Xp21. Boys with AHC often do not undergo puberty owing to hypogonadotropic hypogonadism caused by the same mutated *DAX1* gene. **Cryptorchidism,** sometimes noted in these boys, is probably an early manifestation of hypogonadotropic hypogonadism, but often testicular function in infants is normal, with a typical or even an unusually prolonged testosterone surge in the 1st mo of life.

AHC occasionally occurs as part of a **contiguous gene deletion** syndrome together with Duchenne muscular dystrophy, glycerol kinase deficiency, cognitive impairment, or a combination of these conditions.

Table 575-3 Frequencies of Etiologies of Primary Adrenal Insufficiency

ETIOLOGY		AGE AT DIAGNOSIS
Congenital adrenal hyperplasia	59%	Infancy
Autoimmune	16%	Childhood-adolescence
APECED (autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy)	6%	Childhood-adolescence
Adrenoleukodystrophy	4%	Childhood-adolescence
Isolated glucocorticoid deficiency	4%	Infancy
Idiopathic	4%	Childhood
Syndromes	3%	Infancy
X-linked adrenal hypoplasia congenita	2%	Infancy-childhood
Hemorrhage	1%	Infancy

Data from Perry R, Kecha O, Paquette J, et al. Primary adrenal insufficiency in children: twenty years' experience at the Sainte-Justine Hospital, Montreal. J Clin Endocrinol Metab *90:3243–3250, 2005; Hsieh S, White PC. Presentation of primary adrenal insufficiency in childhood.* J Clin Endocrinol Metab *96:E925–E928, 2011.*

Other Genetic Causes of Adrenal Hypoplasia

The transcription factor SF-1 is required for adrenal and gonadal development (see Chapter 574). Males with a heterozygous mutation in SF-1 *(NR5A1)* have impaired development of the testes despite the presence of a normal copy of the gene on the other chromosome and can appear to be female, similar to patients with lipoid adrenal hyperplasia (see Chapter 576). Rarely, such patients have adrenal insufficiency as well.

Adrenal hypoplasia is also occasionally seen in patients with Pallister-Hall syndrome caused by mutations in the GLI3 oncogene (see Chapter 575).

Adrenoleukodystrophy

In adrenoleukodystrophy (ALD), adrenocortical deficiency is associated with demyelination in the central nervous system (see Chapters 86.2 and 599.3). High levels of very-long-chain fatty acids are found in tissues and body fluids, resulting from their impaired β-oxidation in the peroxisomes.

The most common form of ALD is an X-linked disorder with various presentations. The most common clinical picture is of a degenerative neurologic disorder appearing in childhood or adolescence and progressing to severe dementia and deterioration of vision, hearing, speech, and gait, with death occurring within a few years. Neurologic symptoms may be subtle at onset, sometimes consisting only of behavioral changes or deteriorating academic performance. Generalized but incomplete alopecia, resembling that of chemotherapy, is a characteristic but inconsistent finding. A milder form of X-linked ALD is adrenomyeloneuropathy, which begins in later adolescence or early adulthood. Patients may have evidence of adrenal insufficiency before, at the time of, or after neurologic symptoms develop, often with years separating their presentation. X-linked ALD is caused by mutations in the *ABCD1* gene located on Xq28. The gene encodes a transmembrane transporter involved in the importation of very-long-chain fatty acids into peroxisomes. More than 400 mutations have been described in patients with X-linked ALD. Clinical phenotypes can vary even within families, perhaps owing to modifier genes or other unknown factors. There is no correlation between the degree of neurologic impairment and severity of adrenal insufficiency. Prenatal diagnosis by DNA analysis and family screening by very-long-chain fatty acid assays and mutation analysis are available. Women who are heterozygous carriers of the X-linked ALD gene can develop symptoms in midlife or later; adrenal insufficiency is rare.

Neonatal ALD is a rare autosomal recessive disorder. Infants have neurologic deterioration and have or acquire evidence of adrenocortical dysfunction. Most patients have severe, progressive cognitive impairment and die before 5 yr of age. This disorder is a subset of Zellweger (cerebrohepatorenal) syndrome, in which peroxisomes do not develop at all owing to mutations in any of several genes (*PEX5, PEX1, PEX10, PEX13,* and *PEX26*) controlling the development of this organelle.

Familial Glucocorticoid Deficiency

Familial glucocorticoid deficiency is a form of chronic adrenal insufficiency characterized by isolated deficiency of glucocorticoids, elevated levels of ACTH, and generally normal aldosterone production, although salt-losing manifestations as are present in most other forms of adrenal insufficiency occasionally occur. Patients mainly have hypoglycemia, seizures, and increased pigmentation during the 1st decade of life. The disorder affects both sexes equally and is inherited in an autosomal recessive manner. There is marked adrenocortical atrophy with relative sparing of the zona glomerulosa. Mutations in the gene for the ACTH receptor *(MCR2)* have been described in approximately 25% of these patients, most of which affect trafficking of receptor molecules from the endoplasmic reticulum to the cell surface. Another 20% of cases are caused by mutations in *MRAP,* which encodes a melanocyte receptor accessory protein required for this trafficking. Recently, mutations at new genetic loci have been identified, including

the minichromosome maintenance-deficient 4 homolog *(MCM4)* and nicotinamide nucleotide transhydrogenase *(NNT)*. These genes are involved in DNA replication and antioxidant defense, respectively. Patients with *MCM4* mutations also have growth failure, increased chromosomal breakage, and natural killer cell deficiency.

Another syndrome of ACTH resistance occurs in association with **achalasia** of the gastric cardia and **alacrima (triple A** or **Allgrove syndrome).** These patients often have a progressive neurologic disorder that includes autonomic dysfunction, intellectual disability, motor neuropathy, and occasional deafness. This syndrome is also inherited in an autosomal recessive fashion, and the *AAAS* gene has been mapped to chromosome 12q13. The encoded protein, aladin, might help regulate nucleocytoplasmic transport of other proteins.

Type I Autoimmune Polyendocrinopathy

Although autoimmune Addison disease most often occurs sporadically (see "Autoimmune Addison Disease" in Chapter 575.1), it can occur as a component of 2 syndromes, each consisting of a constellation of autoimmune disorders (see Chapter 566). **Type I autoimmune polyendocrinopathy (APS-1),** also known as *autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy* (APECED) syndrome, is inherited in a mendelian autosomal recessive manner, whereas APS-2 (see "Autoimmune Addison Disease" in Chapter 575.1) has complex inheritance. **Chronic mucocutaneous candidiasis** is most often the first manifestation of APS-1, followed by hypoparathyroidism and then by Addison disease, which typically develops in early adolescence. Other closely associated autoimmune disorders include gonadal failure, alopecia, vitiligo, keratopathy, enamel hypoplasia, nail dystrophy, intestinal malabsorption, and chronic active hepatitis. Hypothyroidism and type 1 diabetes mellitus occur in less than 10% of affected patients. Some components of the syndrome continue to develop as late as the 5th decade. Patients with APS-1 may have autoantibodies to the adrenal cytochrome P450 enzymes CYP21, CYP17, and CYP11A1. The presence of such antibodies indicates a high likelihood of the development of Addison disease or, in female patients, ovarian failure. Adrenal failure can evolve rapidly in APS-1; death in patients with a previous diagnosis and unexplained deaths in siblings of patients with APS-1 have been reported, indicating the need to closely monitor patients with APS-1 and to thoroughly evaluate apparently unaffected siblings of patients with this disorder.

The gene affected in APS-1 is designated autoimmune regulator-1 *(AIRE1);* it has been mapped to chromosome 21q22.3. The *AIRE1* gene encodes a transcription factor that controls the expression of many proteins within the thymus, thus playing a critical role in the generation of immune tolerance. Many different mutations in the *AIRE1* gene have been described in patients with APS-1, with 2 mutations (R257X and a 3-bp deletion) being most common. There has been autosomal dominant transmission in 1 kindred owing to a specific missense mutation (G228W).

Disorders of Cholesterol Synthesis and Metabolism

Patients with disorders of cholesterol synthesis or metabolism, including abetalipoproteinemia with deficient lipoprotein B-containing lipoproteins, and familial hypercholesterolemia, with decreased or impaired low-density lipoprotein receptors, have limited adrenocortical function. Adrenal insufficiency has been reported in patients with **Smith-Lemli-Opitz syndrome**, an autosomal recessive disorder manifesting with facial anomalies, microcephaly, limb anomalies, and developmental delay (see Chapter 86.3). Mutations in the gene coding for sterol Δ^7-reductase, mapped to 11q12-q13, resulting in impairment of the final step in cholesterol synthesis with marked elevation of 7-dehydrocholesterol, abnormally low cholesterol, and adrenal insufficiency, have been identified in Smith-Lemli-Opitz syndrome. **Wolman disease** is a rare autosomal recessive disorder caused by mutations in the gene encoding human lysosomal acid lipase on chromosome 10q23.2-23.3. Cholesteryl esters accumulate in lysosomes in most organ systems, leading to organ failure. Infants during the 1st or 2nd mo of life have hepatosplenomegaly, steatorrhea, abdominal distention, and failure to thrive. Adrenal insufficiency and bilateral adrenal calcification are present, and death usually occurs in the 1st yr of life.

Corticosteroid-Binding Globulin Deficiency and Decreased Cortisol-Binding Affinity

Corticosteroid-binding globulin deficiency and decreased cortisol-binding affinity result in low levels of plasma cortisol but normal urinary free cortisol and normal plasma ACTH levels. A high prevalence of hypotension and fatigue has been reported in some adults with abnormalities of corticosteroid-binding globulin deficiency.

ACQUIRED ETIOLOGIES

Autoimmune Addison Disease

The most common cause of Addison disease is autoimmune destruction of the glands. The glands may be so small that they are not visible at autopsy, and only remnants of tissue are found in microscopic sections. Usually, the medulla is not destroyed, and there is marked lymphocytic infiltration in the area of the former cortex. In advanced disease, all adrenocortical function is lost, but early in the clinical course, isolated cortisol deficiency can occur. Most patients have **antiadrenal cytoplasmic antibodies** in their plasma; 21-hydroxylase (CYP21) is the most commonly occurring biochemically defined autoantigen.

Addison disease can occur as a component of 2 autoimmune polyendocrinopathy syndromes. Type I (APS-1) was discussed previously. **Type II autoimmune polyendocrinopathy (APS-2)** consists of Addison disease associated with autoimmune thyroid disease (Schmidt syndrome) or type 1 diabetes (Carpenter syndrome). Gonadal failure, vitiligo, alopecia, and chronic atrophic gastritis, with or without pernicious anemia, can occur. Frequencies of the human leukocyte antigen (HLA)-D3 and HLA-D4 alleles are increased in these patients and appear to confer an increased risk for development of this disease; particular alleles at the major histocompatibility complex class I chain–related genes A and B *(MICA* and *MICB)* also are associated with this disorder. Polymorphisms in genes involved in other autoimmune disorders have been inconsistently associated with primary adrenal insufficiency, and their contribution to its pathogenesis must be regarded as uncertain. These include the class II, major histocompatibility complex, transactivator (*CIITA*), C-type lectin domain family 16, member A (*CLEC16A*), and protein tyrosine phosphatase, nonreceptor type 22 (*PTPN22*). The disorder is most common in middle-aged women and can occur in many generations of the same family. Antiadrenal antibodies, specifically antibodies to the CYP21, CYP17, and CYP11A1 enzymes, are also found in these patients. Autoimmune adrenal insufficiency may also be seen in patients with celiac disease (see Chapter 338.2).

Infection

Tuberculosis was a common cause of adrenal destruction in the past but is much less prevalent now. The most common infectious etiology for adrenal insufficiency is meningococcemia (see Chapter 191); adrenal crisis from this cause is referred to as the Waterhouse-Friderichsen syndrome. Patients with AIDS can have a variety of subclinical abnormalities in the hypothalamic-pituitary-adrenal axis, but frank adrenal insufficiency is rare. However, drugs used in the treatment of AIDS can affect adrenal hormone homeostasis.

Drugs

Ketoconazole, an antifungal drug, can cause adrenal insufficiency by inhibiting adrenal enzymes. Mitotane (o,p′-DDD), used in the treatment of adrenocortical carcinoma and refractory Cushing syndrome (see Chapters 577 and 579), is cytotoxic to the adrenal cortex and can also alter extraadrenal cortisol metabolism. Signs of adrenal insufficiency occur in a substantial percentage of patients treated with mitotane. Etomidate, used in the induction and maintenance of general anesthesia, inhibits 11β-hydroxylase (CYP11B1), and a single induction dose can block cortisol synthesis for 4-8 hr or longer. This may be problematic in severely stressed patients, particularly if repeated doses

are used in a critical care setting. Atlhough not themselves a cause of adrenal insufficiency, rifampicin and anticonvulsive drugs such as phenytoin and phenobarbital reduce the effectiveness and bioavailability of corticosteroid replacement therapy by inducing steroid metabolizing enzymes in the liver.

Hemorrhage into Adrenal Glands

Hemorrhage into adrenal glands can occur in the neonatal period as a consequence of a difficult labor (especially breech presentation), or its etiology might not be apparent (Fig. 575-1). An incidence rate of 3 in 100,000 live births has been suggested. The hemorrhage may be sufficiently extensive to result in death from exsanguination or hypoadrenalism. An abdominal mass, anemia, unexplained jaundice, or scrotal hematoma may be the presenting sign. Often, the hemorrhage is asymptomatic initially and is identified later by calcification of the adrenal gland. Fetal adrenal hemorrhage has also been reported. Postnatally, adrenal hemorrhage most often occurs in patients being treated with anticoagulants. It can also occur as a result of child abuse.

Clinical Manifestations

Primary adrenal insufficiency leads to cortisol and often aldosterone deficiency. The signs and symptoms of adrenal insufficiency are most easily understood in the context of the normal actions of these hormones (see Chapter 574; Table 575-4).

Hypoglycemia is a prominent feature of adrenal insufficiency. It is often accompanied by ketosis as the body attempts to use fatty acids as an alternative energy source. Ketosis is aggravated by anorexia, nausea, and vomiting, all of which occur frequently.

Cortisol deficiency decreases cardiac output and vascular tone; moreover, catecholamines such as epinephrine have decreased inotropic and pressor effects in the absence of cortisol. These problems are initially manifested as orthostatic hypotension in older children and can progress to frank shock in patients of any age. They are exacerbated by aldosterone deficiency, which results in hypovolemia owing to decreased resorption of sodium in the distal nephron.

Hypotension and decreased cardiac output decrease glomerular filtration and thus decrease the ability of the kidney to excrete free water. Vasopressin (AVP) is secreted by the posterior pituitary in response to hypotension and also as a direct consequence of lack of inhibition by cortisol. These factors decrease plasma osmolality and lead in particular to hyponatremia. Hyponatremia is also caused by aldosterone deficiency and may be much worse when both cortisol and aldosterone are deficient.

In addition to hypovolemia and hyponatremia, aldosterone deficiency causes hyperkalemia by decreasing potassium excretion

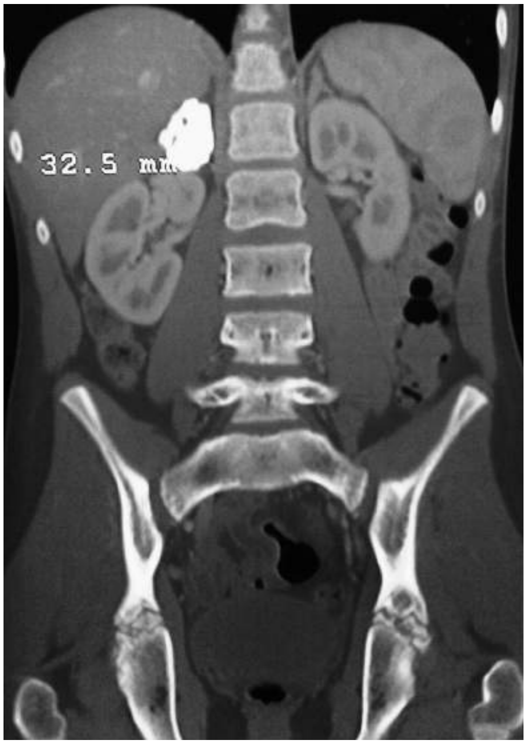

Figure 575-1 Coronal plane of contrast-enhanced computed tomography confirming intraadrenal localization of a round hyperdense lesion compatible with a large calcification. *(From Llano JP, Beaufils E, Nicolino M: Uncommon cause of large paravertebral calcification in a child.* J Pediatr *162:881, 2013, Fig. 2.)*

Table 575-4 Clinical Manifestations and Biochemical Findings in Adrenal Insufficiency

	PATHOPHYSIOLOGIC MECHANISM	PREVALENCE (%)*
SYMPTOMS		
Fatigue	Glucocorticoid deficiency	90
Anorexia, weight loss	Glucocorticoid deficiency	90
Nausea, vomiting	Glucocorticoid deficiency, mineralocorticoid deficiency	90
Salt craving (primary adrenal insufficiency only)	Mineralocorticoid deficiency	20
Myalgia or joint pain	Glucocorticoid deficiency	
SIGNS		
Low blood pressure, orthostatic hypotension	Mineralocorticoid deficiency, glucocorticoid deficiency	70-100%
Skin or mucosal hyperpigmentation (primary adrenal insufficiency only)	Excess of proopiomelanocortin-derived peptides	70
LABORATORY FINDINGS		
Hyponatremia	Mineralocorticoid deficiency, glucocorticoid deficiency (leading to decreased free water excretion)	90
Hyperkalemia (primary adrenal insufficiency only)	Mineralocorticoid deficiency	50
Hypoglycemia	Glucocorticoid deficiency	30
Ketosis	Glucocorticoid deficiency	30
Low random cortisol level	Glucocorticoid deficiency	80
Eosinophilia, lymphocytosis	Glucocorticoid deficiency	
High ACTH level (primary adrenal insufficiency only)	Glucocorticoid deficiency	100
High plasma renin activity (primary adrenal insufficiency only)	Mineralocorticoid deficiency	100

*Prevalence data are for primary insufficiency only. Blanks indicate that no pediatric prevalence data are available.

Data from Hsieh S, White PC. Presentation of primary adrenal insufficiency in childhood. J Clin Endocrinol Metab *96:E925–E928, 2011*

in the distal nephron. Cortisol deficiency alone does not cause hyperkalemia.

Cortisol deficiency decreases negative feedback on the hypothalamus and pituitary, leading to increased secretion of ACTH. Hyperpigmentation is caused by ACTH and other peptide hormones (γ-melanocyte–stimulating hormone) arising from the ACTH precursor proopiomelanocortin. In patients with a fair complexion, the skin can have a bronze cast. Pigmentation may be more prominent in skin creases, mucosa, and scars. In dark-skinned patients, it may be most readily appreciated in the gingival and buccal mucosa.

The clinical presentation of adrenal insufficiency depends on the age of the patient, whether both cortisol and aldosterone secretion are affected, and to some extent on the underlying etiology. The most common causes in early infancy are inborn errors of steroid biosynthesis, sepsis, AHC, and adrenal hemorrhage. Infants have a relatively greater requirement for aldosterone than do older children, possibly owing to immaturity of the kidney and also to the low sodium content of human breast milk and infant formula. Hyperkalemia, hyponatremia, and hypoglycemia are prominent presenting signs of adrenal insufficiency in infants. Ketosis is not consistently present because infants generate ketones less well than do older children. Hyperpigmentation is not usually seen because this takes weeks or months to develop, and orthostatic hypotension is obviously difficult to demonstrate in infants.

Infants can become ill very quickly. There may be only a few days of decreased activity, anorexia, and vomiting before critical electrolyte abnormalities develop.

In older children with Addison disease, symptoms include muscle weakness, malaise, anorexia, vomiting, weight loss, and orthostatic hypotension. These may be of insidious onset. It is not unusual to elicit, in retrospect, an episodic history spanning years with symptoms being noticeable only during intercurrent illnesses. Such patients can present with acute decompensation **(adrenal crisis)** during relatively minor infectious illnesses. *Some of these patients have been initially misdiagnosed with chronic fatigue syndrome, postmononucleosis syndrome, chronic Lyme disease, or psychiatric disorders (depression or anorexia nervosa).*

Hyperpigmentation is often, but not necessarily, present. Hyponatremia is present at diagnosis in almost 90% of patients. Hyperkalemia tends to occur later in the course of the disease in older children than in infants and is present in only half of patients at diagnosis. Normal potassium levels must never be presumed to rule out primary adrenal insufficiency.

Hypoglycemia and ketosis are common. Thus, the clinical presentation can be easily confused with gastroenteritis or other acute infections. Chronicity of symptoms can alert the clinician to the possibility of Addison disease, but this diagnosis should be considered in any child with orthostatic hypotension, hyponatremia, hypoglycemia, and ketosis. Salt craving is seen in primary adrenal insufficiency with mineralocorticoid deficiency. Fatigue, myalgias, fever, eosinophilia, lymphocytosis, hypercalcemia, and anemia may be noted with glucocorticoid deficiency.

LABORATORY FINDINGS

Hypoglycemia, ketosis, hyponatremia, and hyperkalemia have been discussed. An electrocardiogram is useful for quickly detecting hyperkalemia in a critically ill child. Acidosis is often present, and the blood urea nitrogen level is elevated if the patient is dehydrated.

Cortisol levels are sometimes at the low end of the normal range but are invariably low when the patient's degree of illness is considered. ACTH levels are high in primary adrenal insufficiency but can take time to be reported by the laboratory. Similarly, aldosterone levels may be within the normal range but inappropriately low considering the patient's hyponatremia, hyperkalemia, and hypovolemia. Plasma renin activity is elevated. Blood eosinophils may be increased in number, but this is rarely useful diagnostically.

Urinary excretion of sodium and chloride are increased and urinary potassium is decreased, but these are difficult to assess on random urine samples. Accurate interpretation of urinary electrolytes requires more-prolonged (24 hr) urine collections and knowledge of the patient's sodium and potassium intake.

The **most definitive** test for adrenal insufficiency is measurement of serum levels of cortisol before and after administration of ACTH; resting levels are low and do not increase normally after administration of ACTH. Occasionally, normal resting levels that do not increase after administration of ACTH indicate an absence of adrenocortical reserve. A low initial level followed by a significant response to ACTH can indicate secondary adrenal insufficiency. Traditionally, this test has been performed by measuring cortisol levels before and 30 or 60 min after giving 0.250 mg of cosyntropin (ACTH 1-24) by rapid intravenous infusion. Aldosterone will transiently increase in response to this dose of ACTH and may also be measured. A low-dose test (1 μg ACTH 1-24/1.73 m^2) is a more sensitive test of pituitary-adrenal reserve, but has somewhat lower specificity (more false-positive tests).

DIFFERENTIAL DIAGNOSIS

Upon presentation, Addison disease often needs to be distinguished from more acute illnesses such as gastroenteritis with dehydration or sepsis. Additional testing is directed at identifying the specific cause for adrenal insufficiency. When congenital adrenal hyperplasia is suspected, serum levels of cortisol precursors (17-hydroxyprogesterone) should be measured along with cortisol in an ACTH stimulation test (see Chapter 576). Elevated levels of very-long-chain fatty acids are diagnostic of ALD (see Chapter 599.3). Many genetic etiologies for primary adrenal insufficiency may be identified by direct genetic testing, but it can take many weeks for results to become available. The presence of antiadrenal antibodies suggests an autoimmune pathogenesis. Patients with autoimmune Addison disease must be closely observed for the development of other autoimmune disorders. In children, hypoparathyroidism is the most commonly associated disorder, and it is suspected if hypocalcemia and elevated phosphate levels are present.

Ultrasonography (which requires an experienced operator), CT, or MRI can help define the size of the adrenal glands.

TREATMENT

Treatment of acute adrenal insufficiency must be immediate and vigorous. If the diagnosis of adrenal insufficiency has not been established, a blood sample should be obtained before therapy to determine electrolytes, glucose, ACTH, cortisol, aldosterone, and plasma renin activity. If the patient's condition permits, an ACTH stimulation test can be performed while initial fluid resuscitation is under way. An intravenous solution of 5% glucose in 0.9% saline should be administered to correct hypoglycemia, hypovolemia, and hyponatremia. Hypotonic fluids (e.g., 5% glucose in water or 0.2% saline) must be avoided because they can precipitate or exacerbate hyponatremia. If hyperkalemia is severe, it can require treatment with intravenous calcium and/or bicarbonate, intrarectal potassium-binding resin (Kayexalate), or intravenous infusion of glucose and insulin. A water-soluble form of hydrocortisone, such as hydrocortisone sodium succinate, should be given intravenously. As much as 10 mg for infants, 25 mg for toddlers, 50 mg for older children, and 100 mg for adolescents should be administered as a bolus and a similar total amount given in divided doses at 6 hr intervals for the 1st 24 hr. These doses may be reduced during the next 24 hr if progress is satisfactory. Adequate fluid and sodium repletion is achieved by intravenous saline administration, aided by the mineralocorticoid effect of high doses of hydrocortisone.

Particular caution should be exercised in the rare patient with concomitant adrenal insufficiency and hypothyroidism, because thyroxine can increase cortisol clearance. Thus, an adrenal crisis may be precipitated if hypothyroidism is treated without first ensuring adequate glucocorticoid replacement.

After the acute manifestations are under control, most patients require chronic replacement therapy for their cortisol and aldosterone deficiencies. *Hydrocortisone (cortisol) may be given orally in daily doses of 10 mg/m^2/24 hr in 3 divided doses; some patients require 15 mg/m^2/24 hr to minimize fatigue,* especially in the morning.

Timed-release preparations of hydrocortisone are undergoing clinical trials but are not yet generally available. *Equivalent doses (20-25% of the hydrocortisone dose) of prednisone or prednisolone may be divided and given twice daily*. ACTH levels may be used to monitor adequacy of glucocorticoid replacement in primary adrenal insufficiency; in congenital adrenal hyperplasia, levels of precursor hormones are used instead (see Chapter 576). Blood samples for monitoring should be obtained at a consistent time of day and in a consistent relation to (i.e., before or after) the hydrocortisone dose. Normalizing ACTH levels is unnecessary and can require excessive doses of hydrocortisone; generally morning ACTH levels high in the normal range to 3-4 times normal are satisfactory. Because untreated or severely undertreated patients can acutely decompensate during relatively minor illnesses, assessment of symptoms (or lack thereof) must not be used as a substitute for biochemical monitoring. During situations of stress, such as periods of infection or minor operative procedures, the dose of hydrocortisone should be increased 2-3–fold. Major surgery under general anesthesia requires high intravenous doses of hydrocortisone similar to those used for acute adrenal insufficiency.

If aldosterone deficiency is present, *fludrocortisone, a synthetic mineralocorticoid, is given orally in doses of 0.05-0.2 mg daily.* Measurements of plasma renin activity are useful in monitoring the adequacy of mineralocorticoid replacement. Chronic overdosage with glucocorticoids leads to obesity, short stature, and osteoporosis, whereas overdosage with fludrocortisone results in hypertension and occasionally hypokalemia.

Replacement of dehydroepiandrosterone (DHEA) in adults remains controversial; prepubertal children do not normally secrete large amounts of DHEA. Many adults with Addison disease complain of having decreased energy, and replacing DHEA can improve this problem, particularly in women in whom adrenal androgens represent approximately 50% of total androgen secretion.

Additional therapy might need to be directed at the underlying cause of the adrenal insufficiency in regard to infections and certain metabolic defects. Therapeutic approaches to ALD include administration of glycerol trioleate and glycerol trierucate (Lorenzo's oil), bone marrow transplantation, and lovastatin (see Chapter 599.3).

575.2 Secondary and Tertiary Adrenal Insufficiency

Perrin C. White

ETIOLOGY

Abrupt Cessation of Administration of Corticosteroids

Secondary adrenal insufficiency most commonly occurs when the hypothalamic-pituitary-adrenal axis is suppressed by prolonged administration of high doses of a potent glucocorticoid and that agent is suddenly withdrawn or the dose is tapered too quickly. Patients at risk for this problem include those with leukemia, asthma (particularly when patients are transitioned from oral to inhaled corticosteroids), and collagen vascular disease or other autoimmune conditions and those who have undergone tissue transplants or neurosurgical procedures. The maximal duration and dosage of glucocorticoid that can be administered before encountering this problem is not known, but it is assumed that high-dose glucocorticoids (the equivalent of >10 times physiologic cortisol secretion) can be administered for at least 1 wk without requiring a subsequent taper of dose. On the other hand, when high doses of dexamethasone are given to children with leukemia, it can take up to 2 mo or longer after therapy is stopped before tests of adrenal function return to normal. Signs and symptoms of adrenal insufficiency are most likely in patients who are subsequently subjected to stresses such as severe infections or additional surgical procedures.

Corticotropin (Adrenocorticotropic Hormone) Deficiency

Pituitary or hypothalamic dysfunction can cause corticotropin deficiency (see Chapter 557), usually associated with deficiencies of other pituitary hormones such as growth hormone and thyrotropin. Destructive lesions in the area of the pituitary, such as craniopharyngioma and germinoma, are the most common causes of corticotropin deficiency. In many cases, the pituitary or hypothalamus is further damaged during surgical removal or radiotherapy of tumors in the midline of the brain. Traumatic brain injury (see Chapter 710) frequently causes pituitary dysfunction, especially in the first days after the injury. However, corticotropin deficiency is difficult to detect then owing to frequent use of high doses of dexamethasone to minimize brain swelling, and permanent corticotropin deficiency is unusual after traumatic brain injury. In rare instances, autoimmune hypophysitis is the cause of corticotropin deficiency.

Congenital lesions of the pituitary also occur. The pituitary alone may be affected, or additional midline structures may be involved, such as the optic nerves or septum pellucidum. The latter type of abnormality is termed **septooptic dysplasia,** or de Morsier syndrome (see Chapter 591.9). More-severe developmental anomalies of the brain, such as anencephaly and holoprosencephaly, can also affect the pituitary. These disorders are usually sporadic, although a few cases of autosomal recessive inheritance have occurred. Isolated deficiency of corticotropin has been reported, including in several sets of siblings. Patients with multiple pituitary hormone deficiencies caused by mutations in the *PROP1* gene have been described with progressive ACTH/cortisol deficiency. Isolated deficiency of corticotropin-releasing hormone has been documented in an Arab kindred as an autosomal recessive trait.

It was recently recognized that up to 60% of children with **Prader-Willi syndrome** (see Chapter 81.8) have some degree of secondary adrenal insufficiency as assessed by provocative testing with metyrapone (see "Laboratory Findings" in Chapter 575.2), although diurnal cortisol levels are normal. The clinical significance of this finding is uncertain, but it might contribute to the relatively high incidence of sudden death with infectious illness that occurs in this population. Although it is not yet a standard of care, some endocrinologists advocate treating patients who have Prader-Willi syndrome with hydrocortisone during febrile illness.

CLINICAL PRESENTATION

Aldosterone secretion is unaffected in secondary adrenal insufficiency because the adrenal gland is, by definition, intact and the renin–angiotensin system is not involved. Thus, signs and symptoms are those of cortisol deficiency. Newborns often have hypoglycemia. Older children can have orthostatic hypotension or weakness. Hyponatremia may be present.

When secondary adrenal insufficiency is the consequence of an inborn or acquired anatomic defect involving the pituitary, there may be signs of associated deficiencies of other pituitary hormones. The penis may be small in male infants if gonadotropins are also deficient. Infants with secondary hypothyroidism are often jaundiced. Children with associated growth hormone deficiency grow poorly after the 1st yr of life.

Some children with pituitary abnormalities have hypoplasia of the midface. Children with optic nerve hypoplasia can have obvious visual impairment. They usually have a characteristic wandering nystagmus, but this is often not apparent until several months of age.

LABORATORY FINDINGS

Because the adrenal glands themselves are not directly affected, the diagnosis of secondary adrenal insufficiency is sometimes challenging. Historical gold standard dynamic tests include insulin-induced hypoglycemia, which provides a potent stress to the entire hypothalamic-pituitary-adrenal (HPA) axis. This test requires constant attendance by a physician and is considered by many endocrinologists to be too dangerous for routine use. A second gold standard test uses metyrapone, a specific inhibitor of steroid 11β-hydroxylase (CYP11B1) to

block cortisol synthesis, thus removing the normal negative feedback of cortisol on ACTH secretion. There are several protocols for this test; one version administers 30 mg/kg of metyrapone orally at midnight, with a blood sample obtained for cortisol and 11-deoxycortisol (the substrate for 11β-hydroxylase) at 8 AM. A low cortisol level (<5 µg/dL) demonstrates adequate suppression of cortisol synthesis, and an 11-deoxycortisol level >7 µg/dL indicates that ACTH has responded normally to the cortisol deficiency by stimulating the adrenal cortex. This test should be used with caution outside the research setting because it can precipitate adrenal crises in patients with marginal adrenal function; the drug is not available in all locales.

At present, the most commonly used test to diagnose secondary adrenal insufficiency is low-dose ACTH stimulation testing (1 µg/1.73 m^2 of cosyntropin given intravenously), the rationale being that there will be some degree of atrophy of the adrenal cortex if normal physiologic ACTH stimulation is lacking. Thus, this test may be falsely negative in cases of acute compromise of the pituitary (e.g., injury or surgery). Such circumstances rarely pose a diagnostic dilemma; in general, this test provides excellent sensitivity and specificity. Although assays vary somewhat, a threshold cortisol level of 18-20 µg/dL 30 min after cosyntropin administration may be used to dichotomize normal and abnormal responses.

At present, there seems to be little reason to use stimulation with corticotropin-releasing hormone instead of ACTH; although the corticotropin-releasing hormone test has the theoretical advantage of testing the ability of the anterior pituitary to respond to this stimulus by secreting ACTH (thus distinguishing secondary and tertiary adrenal insufficiency), in practice it does not provide improved sensitivity and specificity, and the agent is not as widely available.

TREATMENT

Iatrogenic secondary adrenal insufficiency (caused by chronic glucocorticoid administration) is best avoided by use of the smallest effective doses of systemic glucocorticoids for the shortest period of time. When a patient is thought to be at risk, tapering the dose rapidly to a level equivalent to or slightly less than the physiologic replacement (~10 mg/m^2/24 hr of hydrocortisone) and further tapering over several weeks can allow the adrenal cortex to recover without development of signs of adrenal insufficiency. Patients with anatomic lesions of the pituitary should be treated indefinitely with glucocorticoids. Mineralocorticoid replacement is not required. In patients with panhypopituitarism, treating cortisol deficiency can increase free water excretion, thus unmasking central diabetes insipidus. Electrolytes must be monitored carefully when initiating cortisol therapy in panhypopituitary patients.

Bibliography is available at Expert Consult.

575.3 Adrenal Insufficiency in the Critical Care Setting

Perrin C. White

ETIOLOGY

Adrenal insufficiency in the context of critical illness is encountered in up to 20-50% of pediatric patients, often as a transient condition. In many cases, it is considered to be "functional" or "relative" in nature, meaning that cortisol levels are within normal limits but cannot increase sufficiently to meet the demands of critical illness. The causes are heterogeneous, and some were discussed in Chapter 575.1. They include adrenal hypoperfusion from shock, particularly septic shock, as is often seen in meningococcemia. Inflammatory mediators during septic shock, particularly interleukin-6, can suppress ACTH secretion, directly suppress cortisol secretion, or both. Etomidate, used as sedation for intubation, inhibits steroid 11β-hydroxylase and thus blocks cortisol biosynthesis. Neurosurgical patients with closed head trauma, or with tumors that involve the hypothalamus or pituitary, might have ACTH deficiency in the context of panhypopituitarism. Some children have been previously treated with systemic corticosteroids (e.g., children with leukemia) and have suppression of the HPA axis for that reason. In the intensive care nursery, premature infants have not yet developed normal cortisol biosynthetic capacity (see Chapter 574.2) and thus may not be able to secrete adequate amounts of this hormone when ill.

CLINICAL MANIFESTATIONS

Cortisol is required for catecholamines to have their normal pressor effects on the cardiovascular system (see Chapters 574.4 and 574.5). Accordingly, adrenal insufficiency is often suspected in hypotensive patients who do not respond to intravenous pressor agents. Patients may be at increased risk for hypoglycemia or a presentation resembling the syndrome of inappropriate antidiuretic hormone secretion, but these conditions commonly occur in the context of sepsis, and the contribution of adrenal insufficiency may be difficult to distinguish.

LABORATORY FINDINGS

Although low random cortisol levels in severely stressed patients are certainly abnormal, very high levels are also associated with a poor outcome in such patients; the latter situation presumably reflects a maximally stimulated adrenal cortex with diminished reserve. ACTH (cosyntropin) stimulation testing is generally considered the best way to diagnose adrenal insufficiency in this setting (see Chapter 575.1); evidence suggests that the low-dose (1 µg/1.73 m^2) test may be superior to the 250 µg standard dose test, although this remains controversial. Generally, a peak cortisol level <18 µg/dL or an increment of <9 µg/dL from baseline is considered suggestive for adrenal insufficiency in this context. In evaluating cortisol levels, it should be remembered that cortisol in the circulation is normally mostly bound to cortisol-binding globulin; in hypoproteinemic states total cortisol levels may be decreased, whereas free cortisol levels might be normal. It may be prudent to measure free cortisol before initiating treatment when total cortisol is low and albumin is <2.5 g/dL, but such measurements are not readily available in all institutions.

TREATMENT

There are limited data regarding treatment efficacy in critically ill children. Based on studies of both children and adults, it is likely that moderate stress doses of hydrocortisone (e.g., 50 mg/m^2/day) improve responses to pressor agents in patients with shock and documented adrenal insufficiency. It is uncertain if there is a beneficial effect on overall survival. There seems to be no benefit in using pharmacologic doses of potent synthetic glucocorticoids such as dexamethasone.

Bibliography is available at Expert Consult.

575.4 Altered End-Organ Sensitivity to Corticosteroids

Perrin C. White

Diseases can result from altered actions of hormones at their physiologic targets. These may be caused by abnormal metabolism of hormones, mutations in hormone receptors, or defects in cellular effectors (such as ion channels) that are targets of hormone action.

GENERALIZED GLUCOCORTICOID RESISTANCE

Etiology

Patients with generalized glucocorticoid resistance have target-tissue insensitivity to glucocorticoids. The condition is usually inherited in an autosomal dominant manner but sporadic cases occur. Impairment of normal negative feedback of cortisol at the levels of the hypothalamus and pituitary activates the HPA axis with consequent increases in ACTH and cortisol concentrations. Generalized glucocorticoid resistance is caused by mutations in the glucocorticoid receptor (encoded

by the *NR3C1* gene) that impair its action by interfering with ligand binding, DNA binding, transcriptional activation, or some combination of these. Most mutations are heterozygous; glucocorticoid receptors usually bind DNA as dimers, and 3 out of every 4 dimers will contain at least 1 abnormal receptor molecule when a heterozygous mutation is present.

Clinical Manifestations

The excess ACTH secretion causes adrenal hyperplasia with increased production of adrenal steroids with mineralocorticoid activity, including cortisol, deoxycorticosterone, and corticosterone, and also androgens and precursors, including androstenedione, dehydroepiandrosterone, and dehydroepiandrosterone sulfate. The high cortisol concentrations do not cause Cushing syndrome (see Chapter 577) because of the insensitivity to glucocorticoids; conversely, most signs and symptoms of adrenal insufficiency are absent except for the frequent occurrence of chronic fatigue and occasional anxiety (neonatal hypoglycemia was reported in 1 very unusual patient with a homozygous null mutation). On the other hand, the mineralocorticoid and androgen receptors are normally sensitive to their ligands. Signs of mineralocorticoid excess, such as hypertension and hypokalemic alkalosis, are frequently noted. The increased concentrations of adrenal androgens may cause ambiguous genitalia in girls and gonadotropin-independent precocious puberty in children of either gender; acne; hirsutism, and infertility in both sexes; menstrual irregularities in females; and oligospermia in males. Testicular adrenal rest tumors and ACTH-secreting pituitary adenomas occasionally occur.

Laboratory Findings

The diagnosis of generalized glucocorticoid resistance is suggested by elevated serum cortisol concentrations and increased 24 hr urinary free cortisol excretion in the absence of Cushing syndrome. Levels of other adrenal steroids are also increased. Plasma concentrations of ACTH may be normal or high. The circadian pattern of ACTH and cortisol secretion is preserved, although at higher-than-normal concentrations, and there is resistance of the HPA axis to dexamethasone suppression. Sequencing of the *NR3C1* gene can confirm the diagnosis, but is not routinely available.

Differential Diagnosis

Generalized glucocorticoid resistance should be distinguished from relatively mild cases of Cushing syndrome (whether caused by a pituitary adenoma or adrenal tumor, see Chapter 577); the latter is more likely to be associated with excessive weight gain or poor linear growth. Adrenocortical tumors may secrete mineralocorticoids such as deoxycorticosterone and also androgens, but ACTH levels are often suppressed and of course the tumor can usually be visualized with appropriate imaging techniques. Congenital adrenal hyperplasia (see Chapter 576), particularly 11β-hydroxylase deficiency, may present with hypertension and signs of androgen excess, but in that condition cortisol levels are low and levels of cortisol precursors (17-hydroxyprogesterone, 11-deoxycortisol) are elevated. Obese patients may be hypertensive and have hyperandrogenism, but cortisol secretion should be readily suppressed by dexamethasone.

Treatment

The goal of treatment is to suppress the excess secretion of ACTH, thereby suppressing the increased production of adrenal steroids with mineralocorticoid and androgenic activity. This requires administration of high doses of a pure glucocorticoid agonist such as dexamethasone (typically ~20-40 µg/kg/day) with careful titration to suppress endogenous corticosteroid secretion without causing signs of glucocorticoid excess such as excessive weight gain or suppression of linear growth.

CORTISONE REDUCTASE DEFICIENCY

Etiology

Levels of active glucocorticoids in target tissues are modulated by 2 isozymes of 11β-hydroxysteroid dehydrogenase. The 11-HSD2 isozyme converts cortisol to an inactive metabolite, cortisone; the 2 steroids differ in the presence of an 11β-hydroxyl vs an 11-oxo group, respectively. Mutations in this enzyme cause the syndrome of **apparent mineralocorticoid excess**. Conversely, the 11-HSD1 isozyme converts cortisone to cortisol, and so it is sometimes referred to as "cortisone reductase." This isozyme is expressed at high levels in glucocorticoid target tissues, particularly the liver, where it ensures adequate levels of active glucocorticoids (cortisol and corticosterone) to meet metabolic demands without requiring excessive adrenal cortisol secretion.

The 11-HSD1 isozyme is located in the endoplasmic reticulum (i.e., it is a "microsomal" enzyme) and functions as a dimer. It accepts electrons from reduced nicotine–adenine dinucleotide phosphate, which is generated within the endoplasmic reticulum by hexose-6-phosphate dehydrogenase, an enzyme distinct from cytoplasmic glucose-6-phosphate dehydrogenase.

Apparent cortisone reductase deficiency is caused by homozygous mutations in hexose-6-phosphate dehydrogenase that prevent generation of reduced nicotine–adenine dinucleotide phosphate within the endoplasmic reticulum and thus starve 11-HSD1 of its essential cofactor for the reductase reaction. Very rare patients have been reported to have heterozygous mutations in the *HSD11B1* gene encoding 11-HSD1 itself and thus have "true" cortisone reductase deficiency; because the enzyme functions as a homodimer, heterozygous mutations are able to impair three fourths of all dimmers.

Clinical Manifestations

Because circulating cortisone is not converted to cortisol, the circulating half-life of cortisol is decreased and the adrenal cortex must secrete additional cortisol to compensate. This leads to adrenocortical overactivity analogous to, but generally much milder than, that seen in generalized glucocorticoid resistance. This is usually not severe enough to cause hypertension, presenting instead with mild to moderate signs of androgen excess such as hirsutism, oligomenorrhea or amenorrhea, and infertility in females, and precocious pseudopuberty (axillary and pubic hair, and penile enlargement, but not testicular enlargement) in males.

Laboratory Findings

The ratio of cortisol to cortisone in blood is lower than usual. The same is true of urinary metabolites, typically measured as a ratio of the sum of the tetrahydrocortisol and allotetrahydrocortisol excretion to that of tetrahydrocortisone. These determinations are best accomplished by gas chromatography followed by mass spectrometry, and are available in specialized reference laboratories. Absolute levels of cortisol and ACTH are within normal limits.

Differential Diagnosis

Cortisone reductase deficiency has to be distinguished from, and is much less common than, other causes of androgen excess such as polycystic ovarian syndrome and nonclassical congenital adrenal hyperplasia as a result of 21-hydroxylase deficiency.

Treatment

Treatment is aimed at decreasing adrenal overactivity and thus reducing secretion of androgens. This can be accomplished by administration of hydrocortisone.

ALTERED END-ORGAN SENSITIVITY TO MINERALOCORTICOIDS

Pseudohypoaldosteronism

Etiology

Pseudohypoaldosteronism type 1 (PHA1) is a monogenic disease in which aldosterone action is deficient and patients are thus unable to resorb urinary sodium or excrete potassium properly. There are 2 forms. A relatively mild **autosomal dominant** form is caused by mutations in the *NR3C2* gene encoding the human mineralocorticoid receptor. As with generalized glucocorticoid resistance, a heterozygous mutation is sufficient to cause disease because the

mineralocorticoid receptor interacts with DNA as a dimer, and three fourths of the dimers are defective in individuals carrying heterozygous mutations (assuming mutant protein is synthesized). A more-severe **autosomal recessive** form is usually the result of homozygous mutations in the α (*SCNN1A*), β (*SCNN1B*), or γ (*SCNN1G*) subunits of the epithelial Na(+) channel, but 1 reported case of severe autosomal recessive disease was caused by homozygous mutations in *NR3C2*.

PHA1 should not be confused with pseudohypoaldosteronism type 2, a rare mendelian syndrome characterized by hyperkalemia and, in contrast to PHA1, by hypertension from excessive renal salt reabsorption. This disorder is caused by mutations in the renal regulatory kinases, WNK1 and WNK4, or components of an E3 ubiquitin ligase complex Kelch-like 3 (KLHL3) and Cullin 3 (CUL3).

Clinical Manifestations
Infants with PHA1 present with hyperkalemia, hyponatremia, hypovolemia, hypotension, and failure to thrive. In more-severe (usually autosomal recessive) cases, salt loss is not confined to the kidney but instead occurs from most epithelia. Mothers may report that the skin of their affected infants tastes salty. Some infants suffer from **cystic fibrosis–like pulmonary symptoms.** It is often difficult to control electrolyte abnormalities in patients with the autosomal recessive form, leading to frequent hospitalizations and a need for close clinical monitoring.

It is noteworthy that signs and symptoms of aldosterone deficiency tend to remit as the patients get older, particularly in the autosomal dominant form. This is similar to what is seen in actual aldosterone deficiency as occurs in the salt-losing forms of congenital adrenal hyperplasia or aldosterone synthase deficiency. The kidney matures after early infancy to become more efficient at excreting potassium, and whereas breast milk and infant formula are low in sodium, the normal adult Western diet is relatively high in sodium, thus compensating for the renal salt wasting.

Laboratory Findings
Infants have marked hyperkalemia and hyponatremia. Both plasma renin and aldosterone are markedly elevated. Levels of cortisol and ACTH are normal. If hypovolemia is severe, patients may develop prerenal azotemia. The electrocardiogram may include tall peaked T waves with severe hyperkalemia or ventricular tachycardia.

Differential Diagnosis
PHA in infants should be distinguished from other causes of hyperkalemia and hyponatremia. These include renal failure of any cause, congenital adrenal hyperplasia, aldosterone synthase deficiency, and other causes of adrenocortical insufficiency such as AHC. Patients with renal failure will have elevated blood urea nitrogen and creatinine, but these may be seen in severely dehydrated patients with PHA. Patients with any form of adrenal insufficiency in this clinical context will have low or low-normal aldosterone levels (with elevated plasma renin), in contrast to the elevated aldosterone levels seen in PHA. Patients with congenital adrenal hyperplasia have elevated levels of steroid precursors such as 17-hydroxyprogesterone (in patients with 21-hydroxylase deficiency), and patients with most forms of adrenal insufficiency have elevated ACTH levels.

Treatment
Infants must be given dietary sodium supplementation (initially intravenous and then oral), typically approximately 8 mEq/kg/day. Potassium levels in the infant formula often need to be reduced, which may be accomplished by mixing the formula with polystyrene resin (Kayexalate) and then decanting the formula prior to feeding. Fludrocortisone, a synthetic mineralocorticoid, may be efficacious in milder autosomal dominant cases if administered in high doses (titrating up to ~0.5 mg daily). Significant electrolyte abnormalities require treatment with intravenous normal saline and rectal polystyrene resin. Severe hyperkalemia may require glucose and insulin infusions to control.

APPARENT MINERALOCORTICOID EXCESS
Etiology
The syndrome of apparent mineralocorticoid excess is an autosomal recessive disorder caused by mutations in the *HSD11B2* gene encoding the 11-HSD2 isozyme of 11β-hydroxysteroid dehydrogenase. The mineralocorticoid receptor actually has nearly identical affinities for aldosterone (the main mineralocorticoid hormone) and cortisol, yet cortisol is normally only a weak mineralocorticoid in vivo. This is because 11-HSD2 is expressed along with the mineralocorticoid receptor in most target tissues such as the renal cortical collecting duct epithelium. It converts cortisol to cortisone, which is not an active steroid, thus preventing it from occupying the mineralocorticoid receptor. In contrast, aldosterone is not a substrate for the enzyme because its 11β-hydroxyl group forms a hemiketal with the 18-aldehyde group of the steroid and is thus not accessible to the enzyme. Thus, in the absence of 11-HSD2, cortisol is able to efficiently occupy the mineralocorticoid receptor, and because cortisol concentrations are normally far higher than those of aldosterone, this results in signs and symptoms of mineralocorticoid excess.

A similar clinical picture occurs with excessive consumption of licorice or licorice-flavored chewing tobacco; licorice contains compounds including glycyrrhetinic and glycyrrhizic acids that inhibit 11-HSD2. Carbenoxolone, an antihypertensive drug that is not marketed in the United States, has similar effects.

Clinical Manifestations
Affected infants often have some degree of intrauterine growth restriction with birth weights of 2 kg typical for term infants. Infants and children often fail to thrive. Severe hypertension (to ~200/120 mm Hg) is almost always present. In some patients, the hypertension tends to be labile or paroxysmal with severe emotional stress as a precipitating factor. Complications of hypertension have included cerebrovascular accidents. Several patients have died during infancy or adolescence, either from electrolyte imbalances leading to cardiac arrhythmias or from vascular sequelae of hypertension. Hypokalemic alkalosis can eventually cause nephrocalcinosis (often visible on renal ultrasound) and nephrogenic diabetes insipidus leading to polyuria and polydipsia. Deleterious effects on muscle range from elevations in serum creatine phosphokinase to frank rhabdomyolysis. Electrocardiograms show left ventricular hypertrophy.

Laboratory Findings
Hypokalemia and alkalosis are common but not persistent. Sodium levels are generally in the upper part of the reference range. Aldosterone and renin levels are very low because the hypertension and hypervolemia are independent of aldosterone concentrations. Serum cortisol and ACTH levels are generally within normal limits. The serum half-life of cortisol is increased, but the test for this requires a radioactive tracer and is not clinically available. Total urinary excretion of cortisol metabolites is markedly decreased. The urinary ratio of free cortisol to free cortisone is elevated, as is the ratio of urinary tetrahydrocortisol plus allotetrahydrocortisol to tetrahydrocortisone.

Differential Diagnosis
The differential diagnosis includes other forms of severe childhood hypertension such as renal artery anomalies, but relatively few conditions present with suppressed renin and aldosterone levels. Liddle syndrome has a similar presentation but no abnormalities in the steroid profile, typically has an autosomal dominant mode of inheritance, and does not respond to treatment with mineralocorticoid receptor antagonists. Hypertensive forms of congenital adrenal hyperplasia (see Chapter 576) also have suppressed renin and aldosterone levels, but they present with signs of androgen excess (11β-hydroxylase deficiency) or androgen deficiency (17α-hydroxylase deficiency); the latter can be difficult to appreciate in young children. The steroid profiles in congenital adrenal hyperplasia differ from those seen in apparent mineralocorticoid excess syndrome.

Patients with severe Cushing syndrome may have high enough cortisol levels to overwhelm renal 11-HSD2, leading to severe

hypertension with alterations in urinary cortisol-to-cortisone ratios. This occurs most often in patients with the ectopic ACTH syndrome. This generally does not present a diagnostic dilemma, because of the other signs of Cushing syndrome including high cortisol levels.

Treatment

Treatment includes a low-salt diet, potassium supplementation, and mineralocorticoid receptor blockade with spironolactone or eplerenone; a sodium channel blocker, such as amiloride or triamterene may work at least as well. In principle, suppression of cortisol secretion with dexamethasone (which does not bind the mineralocorticoid receptor) should work, but in practice it is much less effective than mineralocorticoid receptor blockade.

LIDDLE SYNDROME

Etiology

Liddle syndrome is a form of hypertension and hypokalemia that is clinically similar to the syndrome of apparent mineralocorticoid excess, but it is inherited in an autosomal dominant manner. It is caused by activating mutations in the β (*SCNN1B*) or γ (*SCNN1G*) subunits of the epithelial sodium channel. Most of these mutations prevent the channel subunits from being ligated to ubiquitin and targeted to the proteosome for degradation, a process that is normally regulated indirectly by aldosterone. The net effect is to increase the number of open channels at the apical surface of epithelial cells of the renal collecting duct, thus facilitating sodium resorption and potassium excretion. This disorder is thus the exact opposite of the autosomal recessive form of pseudohypoaldosteronism discussed previously.

Clinical Manifestations, Laboratory Findings, and Differential Diagnosis

Liddle syndrome is characterized by severe early-onset hypertension and by hypokalemia, which may not be persistent. Aldosterone and renin levels are suppressed but all steroid hormone levels are normal.

The differential diagnosis is the same as that for apparent mineralocorticoid excess.

Treatment

The mainstays of treatment are a low-salt diet, potassium supplementation, and a sodium channel blocker such as amiloride or triamterene. Mineralocorticoid receptor antagonists such as spironolactone are ineffective.

Chapter 576

Congenital Adrenal Hyperplasia and Related Disorders

Perrin C. White

Congenital adrenal hyperplasia (CAH) is a family of autosomal recessive disorders of cortisol biosynthesis (normal adrenal steroidogenesis is discussed in Chapter 574). Cortisol deficiency increases secretion of corticotropin (adrenocorticotropic hormone [ACTH]), which, in turn, leads to adrenocortical hyperplasia and overproduction of intermediate metabolites. Depending on the enzymatic step that is deficient, there may be signs, symptoms, and laboratory findings of mineralocorticoid deficiency or excess; incomplete virilization or precocious puberty in affected males; and virilization or sexual infantilism in affected females (Figs. 576-1 and 576-2 and Table 576-1).

576.1 Congenital Adrenal Hyperplasia Caused by 21-Hydroxylase Deficiency

Perrin C. White

ETIOLOGY

More than 90% of CAH cases are caused by 21-hydroxylase deficiency. This P450 enzyme (CYP21, P450c21) hydroxylates progesterone and 17-hydroxyprogesterone to yield 11-deoxycorticosterone and 11-deoxycortisol, respectively (see Fig. 574-1 in Chapter 574). These conversions are required for synthesis of aldosterone and cortisol, respectively. Both hormones are deficient in the most-severe, "salt-wasting" form of the disease. Slightly less-severely affected patients are able to synthesize adequate amounts of aldosterone but have elevated levels of androgens of adrenal origin; this is termed "simple virilizing disease". These 2 forms are collectively termed classic 21-hydroxylase deficiency. Patients with nonclassic disease have relatively mildly elevated levels of androgens and may be asymptomatic or have signs of androgen excess at any time after birth. Clinical presentation is dependent, in part, on the genotype (see below, "Genetics,") (Table 576-2).

EPIDEMIOLOGY

Classic 21-hydroxylase deficiency occurs in approximately 1 in 15,000-20,000 births in most populations. Approximately 70% of affected infants have the salt-losing form, whereas 30% have the simple virilizing form of the disorder. In the United States, CAH is less common in African-Americans compared with white children (1 : 42,000 vs 1 : 15,500). Nonclassic disease has a prevalence of approximately 1 in 1,000 in the general population, but occurs more frequently in specific ethnic groups such as Ashkenazi Jews and Hispanics.

GENETICS

There are 2 steroid 21-hydroxylase genes—*CYP21P (CYP21A1P, CYP21A)* and *CYP21 (CYP21A2, CYP21B)*—which alternate in tandem with 2 genes for the fourth component of complement (C4A and C4B) in the human leukocyte antigen (HLA) major histocompatibility complex on chromosome 6p21.3 between the HLA-B and HLA-DR loci. Many other genes are located in this cluster. *CYP21* is the active gene; *CYP21P* is 98% identical in DNA sequence to *CYP21* but is a pseudogene because of 9 different mutations. More than 90% of mutations causing 21-hydroxylase deficiency are recombinations between *CYP21* and *CYP21P.* Approximately 20% are deletions generated by unequal meiotic crossing-over between *CYP21* and *CYP21P,* whereas the remainder are nonreciprocal transfers of deleterious mutations from *CYP21P* to *CYP21,* a phenomenon termed gene conversion.

The deleterious mutations in *CYP21P* have different effects on enzymatic activity when transferred to *CYP21.* Several mutations completely prevent synthesis of a functional protein, whereas others are missense mutations (they result in amino acid substitutions) that yield enzymes with 1-50% of normal activity. Disease severity correlates well with the mutations carried by an affected individual; for example, patients with salt-wasting disease usually carry mutations on both alleles that completely destroy enzymatic activity. Patients are frequently compound heterozygotes for different types of mutations (i.e., 1 allele is less-severely affected than the other), in which case the severity of disease expression is largely determined by the activity of the less-severely affected of the 2 alleles.

Closely adjacent to, but on the opposite DNA strand from, *CYP21* is the tenascin-X (*TNX)* gene, which encodes a connective tissue protein. Rarely, deletions of *CYP21* extend into *TNX.* Such patients may have a contiguous gene syndrome (see Chapter 81.1) consisting of CAH and **Ehlers-Danlos syndrome** (see Chapters 484 and 659).

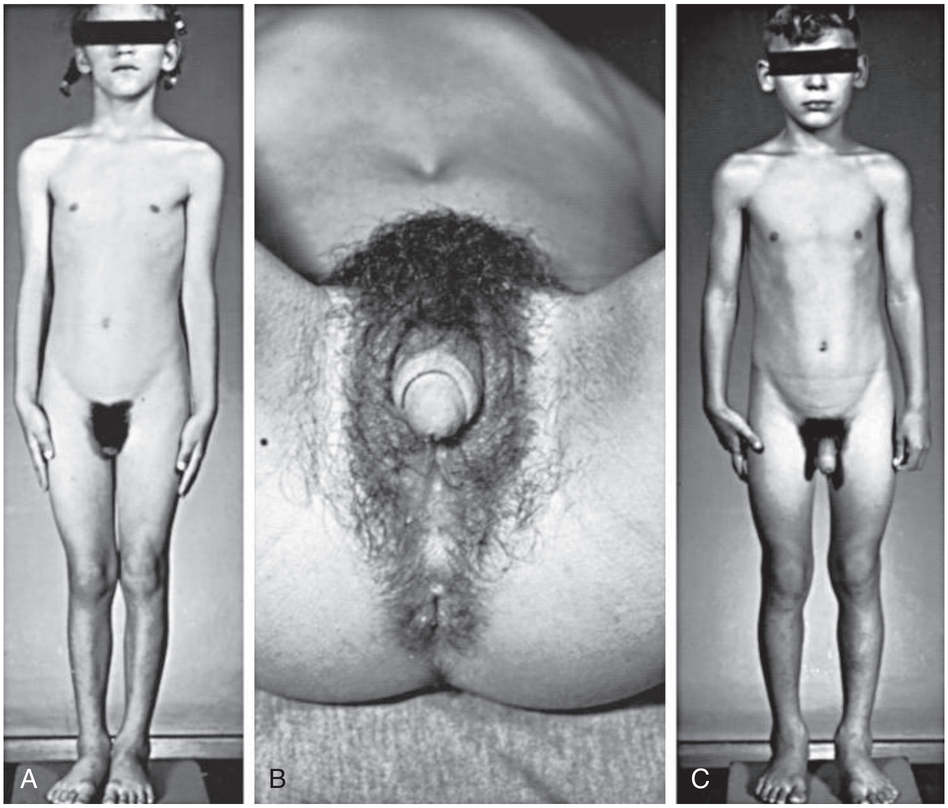

Figure 576-1 A, A 6-yr-old girl with congenital virilizing adrenal hyperplasia. The height age was 8.5 yr, and the bone age was 13 yr. **B,** Notice the clitoral enlargement and labial fusion. **C,** Her 5 yr old brother was not considered to be abnormal by the parents. The height age was 8 yr, and the bone age was 12.5 yr.

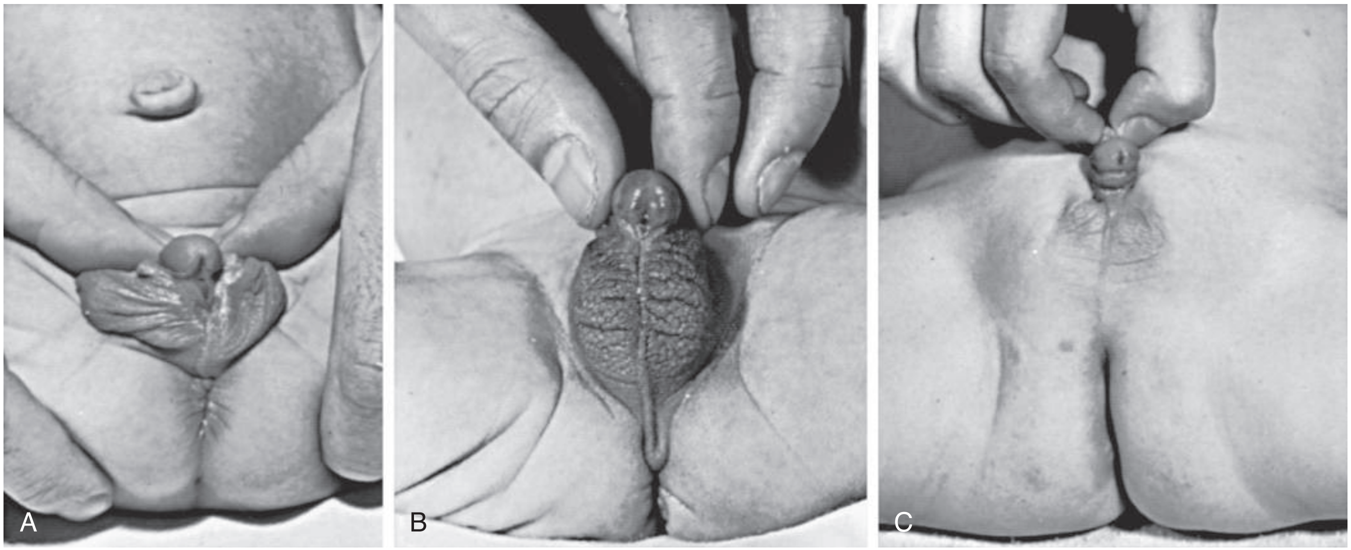

Figure 576-2 Three virilized females with untreated congenital adrenal hyperplasia. All were erroneously assigned male sex at birth, and each had a normal female sex-chromosome complement. Infants **A** and **B** had the salt-wasting form and received the diagnosis early in infancy. Infant **C** was referred at 1 yr of age because of bilateral cryptorchidism. Notice the completely penile urethra; such complete masculinization in females with adrenal hyperplasia is rare; most of these infants have the salt-wasting form.

Table 576-1 Diagnosis and Treatment of Congenital Adrenal Hyperplasia

DISORDER	AFFECTED GENE AND CHROMOSOME	SIGNS AND SYMPTOMS	LABORATORY FINDINGS	THERAPEUTIC MEASURES
21-Hydroxylase deficiency, classic form	*CYP21* 6p21.3	Glucocorticoid deficiency	↓ Cortisol, ↑ACTH ↑↑ Baseline and ACTH-stimulated 17-hydroxy-progesterone	Glucocorticoid (hydrocortisone) replacement
		Mineralocorticoid deficiency (salt-wasting crisis)	Hyponatremia, hyperkalemia ↑ Plasma renin	Mineralocorticoid (fludrocortisone) replacement; sodium chloride supplementation
		Ambiguous genitalia in females	↑ Serum androgens	Vaginoplasty and clitoral recession
		Postnatal virilization in males and females	↑ Serum androgens	Suppression with glucocorticoids
21-Hydroxylase deficiency, nonclassic form	*CYP21* 6p21.3	May be asymptomatic; precocious adrenarche, hirsutism, acne, menstrual irregularity, infertility	↑ Baseline and ACTH-stimulated 17-hydroxyprogesterone ↑ Serum androgens	Suppression with glucocorticoids
11β-Hydroxylase deficiency	*CYP11B1* 8q24.3	Glucocorticoid deficiency	↓ Cortisol, ↑ ACTH ↑↑ Baseline and ACTH-stimulated 11-deoxycortisol and deoxycorticosterone	Glucocorticoid (hydrocortisone) replacement
		Ambiguous genitalia in females	↑ Serum androgens	Vaginoplasty and clitoral recession
		Postnatal virilization in males and females	↑ Serum androgens	Suppression with glucocorticoids
		Hypertension	↓ Plasma renin, hypokalemia	Suppression with glucocorticoids
3β-Hydroxysteroid dehydrogenase deficiency, classic form	*HSD3B2* 1p13.1	Glucocorticoid deficiency	↓ Cortisol, ↑ ACTH ↑↑ Baseline and ACTH-stimulated Δ5 steroids (pregnenolone, 17-hydroxy-pregnenolone, DHEA)	Glucocorticoid (hydrocortisone) replacement
		Mineralocorticoid deficiency (salt-wasting crisis)	Hyponatremia, hyperkalemia ↑ Plasma renin	Mineralocorticoid (fludrocortisone) replacement; sodium chloride supplementation
		Ambiguous genitalia in females and males	↑ DHEA, ↓ androstenedione, testosterone, and estradiol	Surgical correction of genitals and sex hormone replacement as necessary, consonant with sex of rearing
		Precocious adrenarche, disordered puberty	↑ DHEA, ↓ androstenedione, testosterone, and estradiol	Suppression with glucocorticoids
17α-Hydroxylase/17,20-lyase deficiency	*CYP17* 10q24.3	Cortisol deficiency (corticosterone is an adequate glucocorticoid)	↓ Cortisol, ↑ ACTH ↑ DOC, corticosterone Low 17α-hydroxylated steroids; poor response to ACTH	Glucocorticoid (hydrocortisone) administration
		Ambiguous genitalia in males	↓ Serum androgens; poor response to hCG	Orchidopexy or removal of intraabdominal testes; sex hormone replacement consonant with sex of rearing
		Sexual infantilism	↓ Serum androgens or estrogens	Sex hormone replacement consonant with sex of rearing
		Hypertension	↓ Plasma renin; hypokalemia	Suppression with glucocorticoids
Congenital lipoid adrenal hyperplasia	*STAR* 8p11.2	Glucocorticoid deficiency	↑ ACTH Low levels of all steroid hormones, with decreased or absent response to ACTH	Glucocorticoid (hydrocortisone) replacement
		Mineralocorticoid deficiency (salt-wasting crisis)	Hyponatremia, hyperkalemia ↓ Aldosterone, ↑ plasma renin	Mineralocorticoid (fludrocortisone) replacement; sodium chloride supplementation
		Ambiguous genitalia in males	Decreased or absent response to hCG in males	Orchidopexy or removal of intraabdominal testes; sex hormone replacement consonant with sex of rearing
		Poor pubertal development or premature ovarian failure in females	↑ FSH, ↑ LH, ↓ estradiol (after puberty)	Estrogen replacement

Table 576-1 Diagnosis and Treatment of Congenital Adrenal Hyperplasia—cont'd

DISORDER	AFFECTED GENE AND CHROMOSOME	SIGNS AND SYMPTOMS	LABORATORY FINDINGS	THERAPEUTIC MEASURES
P450 oxidoreductase deficiency	*POR* 7q11.3	Glucocorticoid deficiency Ambiguous genitalia in males and females Maternal virilization Antley-Bixler syndrome	↓ Cortisol, ↑ ACTH ↑ Pregnenolone, ↑ progesterone ↑ Serum androgens prenatally, ↓ androgens and estrogens at puberty Decreased ratio of estrogens to androgens	Glucocorticoid (hydrocortisone) replacement Surgical correction of genitals and sex hormone replacement as necessary, consonant with sex of rearing

↓, Decreased; ↑, increased; ↑↑, markedly increased; ACTH, adrenocorticotropic hormone; DHEA, dehydroepiandrosterone; DOC, 11-deoxycorticosterone; FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone.

Table 576-2 Genotype-Phenotype Correlations in Congenital Adrenal Hyperplasia Owing to 21-Hydroxylase Deficiency

MUTATION GROUP	A	B	C
Enzymatic activity, % normal	Nil	1-2%	20-50%
CYP21 mutations (phenotype generally corresponds to the least affected allele)	Gene deletion Exon 3 del 8 bp Exon 6 cluster Q318X R356W Intron 2 splice	I172N	P30L V281L P453S
Severity	Salt wasting	Simple virilizing	Nonclassic
Aldosterone synthesis	Low	Normal	Normal

Virilization	Severe	Moderate to severe	None to Mild
Incidence	1/20,000	1/50,000	1/500

PATHOGENESIS AND CLINICAL MANIFESTATIONS

Aldosterone and Cortisol Deficiency

Because both cortisol and aldosterone require 21-hydroxylation for their synthesis, both hormones are deficient in the most-severe, salt-wasting form of the disease. This form constitutes approximately 70% of cases of classic 21-hydroxylase deficiency. The signs and symptoms of cortisol and aldosterone deficiency, and the pathophysiology underlying them, are essentially those described in Chapter 575. These include progressive weight loss, anorexia, vomiting, dehydration, weakness, hypotension, hypoglycemia, hyponatremia, and hyperkalemia. These problems typically first develop in affected infants at approximately 10-14 days of age. Without treatment, shock, cardiac arrhythmias, and death may occur within days or weeks.

CAH differs from other causes of primary adrenal insufficiency in that precursor steroids accumulate proximal to the blocked enzymatic conversion. Because cortisol is not synthesized efficiently, ACTH levels are high, leading to hyperplasia of the adrenal cortex and levels of precursor steroids that may be hundreds of times normal. In the case of 21-hydroxylase deficiency, these precursors include 17-hydroxyprogesterone and progesterone. Progesterone and perhaps other metabolites act as antagonists of the mineralocorticoid receptor and thus may exacerbate the effects of aldosterone deficiency in untreated patients.

Prenatal Androgen Excess

The most important problem caused by accumulation of steroid precursors is that 17-hydroxyprogesterone is shunted into the pathway for androgen biosynthesis, leading to high levels of androstenedione that are converted outside the adrenal gland to testosterone. This problem begins in affected fetuses by 8-10 wk of gestation and leads to abnormal genital development in females (see Figs. 576-1 and 576-2).

The external genitalia of males and females normally appear identical early in gestation (see Chapter 582). Affected females who are exposed in utero to high levels of androgens of adrenal origin have masculinized external genitalia (see Figs. 576-1 and 576-2). This is manifested by enlargement of the clitoris and by partial or complete labial fusion. The vagina usually has a common opening with the urethra (urogenital sinus). The clitoris may be so enlarged that it resembles a penis; because the urethra opens below this organ, some affected females may be mistakenly presumed to be males with hypospadias and cryptorchidism. The severity of virilization is usually greatest in females with the salt-losing form of 21-hydroxylase deficiency (see Table 576-2). The internal genital organs are normal, because affected females have normal ovaries and not testes and thus do not secrete antimüllerian hormone.

Prenatal exposure of the brain to high levels of androgens may influence subsequent sexually dimorphic behaviors in affected females. Girls may demonstrate aggressive play behavior, tend to be interested in masculine toys such as cars and trucks, and often show decreased interest in playing with dolls. Women may have decreased interest in maternal roles. There is an increased frequency of homosexuality in affected females. Nonetheless, most function heterosexually and do not have gender identity confusion or dysphoria. It is unusual for affected females to assign themselves a male role except in some with the severest degree of virilization.

Male infants appear normal at birth. Thus, the diagnosis may not be made in boys until signs of adrenal insufficiency develop. Because

patients with this condition can deteriorate quickly, infant boys are more likely to die than infant girls. For this reason, all 50 American states and many countries have instituted newborn screening for this condition (see "Newborn Screening" in Chapter 576.2).

Postnatal Androgen Excess

Untreated or inadequately treated children of both sexes develop additional signs of androgen excess after birth. Boys with the simple virilizing form of 21-hydroxylase deficiency often have a delayed diagnosis because they appear normal and rarely develop adrenal insufficiency.

Signs of androgen excess include rapid somatic growth and accelerated skeletal maturation. Thus, affected patients are tall in childhood but premature closure of the epiphyses causes growth to stop relatively early, and adult stature is stunted (see Fig. 576-1). Muscular development may be excessive. Pubic and axillary hair may appear, and acne and a deep voice may develop. The penis, scrotum, and prostate may become enlarged in affected boys; however, the **testes are usually prepubertal** in size so that they appear relatively small in contrast to the enlarged penis. Occasionally, ectopic adrenocortical cells in the testes of patients become hyperplastic similarly to the adrenal glands, producing testicular adrenal rest tumors (see Chapter 584). The clitoris may become further enlarged in affected females (see Fig. 576-1). Although the internal genital structures are female, breast development and menstruation may not occur unless the excessive production of androgens is suppressed by adequate treatment.

Similar but usually milder signs of androgen excess may occur in **nonclassic 21-hydroxylase deficiency** (see Table 576-2). In this attenuated form, cortisol and aldosterone levels are normal and affected females have normal genitals at birth. Males and females may present with precocious pubarche and early development of pubic and axillary hair. Hirsutism, acne, menstrual disorders, and infertility may develop later in life, but many females and males are completely asymptomatic.

Adrenomedullary Dysfunction

Development of the adrenal medulla requires exposure to the extremely high cortisol levels normally present within the adrenal gland. Thus patients with classic CAH have abnormal adrenomedullary function, as evidenced by blunted epinephrine responses, decreased blood glucose, and lower heart rates with exercise. Ability to exercise is unimpaired and the clinical significance of these findings is uncertain. Adrenomedullary dysfunction may exacerbate the cardiovascular effects of cortisol deficiency in untreated or undertreated patients.

LABORATORY FINDINGS

See Table 576-1.

Patients with salt-losing disease have typical laboratory findings associated with cortisol and aldosterone deficiency, including hyponatremia, hyperkalemia, metabolic acidosis, and, often, hypoglycemia, but these abnormalities can take 10-14 days or longer to develop after birth. Blood levels of **17-hydroxyprogesterone** are markedly elevated. However, levels of this hormone are high during the 1st 2-3 days of life even in unaffected infants and especially if they are sick or premature. After infancy, once the circadian rhythm of cortisol is established, 17-hydroxyprogesterone levels vary in the same circadian pattern, being highest in the morning and lowest at night. Blood levels of cortisol are usually low in patients with the salt-losing type of disease. They are often normal in patients with simple virilizing disease but inappropriately low in relation to the ACTH and 17-hydroxyprogesterone levels. In addition to 17-hydroxyprogesterone, levels of androstenedione and testosterone are elevated in affected females; testosterone is not elevated in affected males, because normal infant males have high testosterone levels compared with those seen later in childhood. Levels of urinary 17-ketosteroids and pregnanetriol are elevated but are now rarely used clinically because blood samples are easier to obtain than 24 hr urine collections. ACTH levels are elevated but have no diagnostic utility over 17-hydroxyprogesterone levels. Plasma levels of renin are elevated, and serum aldosterone is inappropriately low for the renin level. However, renin levels are high in normal infants in the 1st few wk of life.

Diagnosis of 21-hydroxylase deficiency is most reliably established by measuring 17-hydroxyprogesterone before and 30 or 60 min after an intravenous bolus of 0.125-0.25 mg of cosyntropin (ACTH 1-24). Nomograms exist that readily distinguish normals and patients with nonclassic and classic 21-hydroxylase deficiency. Heterozygous carriers of this autosomal recessive disorder tend to have higher ACTH-stimulated 17-hydroxyprogesterone levels than genetically unaffected individuals, but there is significant overlap between subjects in these 2 categories. However, in infants with frank electrolyte abnormalities or circulatory instability, it may not be possible or necessary to delay treatment to perform this test, as levels of precursors will be sufficiently elevated on a random blood sample to make the diagnosis.

Genotyping is clinically available and may help confirm the diagnosis, but it is expensive and may take weeks. Because the gene conversions that generate most mutant alleles may transfer more than one mutation, at least one parent should be genotyped as well to determine which mutations lie on each allele.

DIFFERENTIAL DIAGNOSIS

Disorders of sexual development are discussed more generally in Chapter 588. The initial step in evaluating an infant with ambiguous genitals is a thorough physical examination to define the anatomy of the genitals, locate the urethral meatus, palpate the scrotum or labia and the inguinal regions for testes (palpable gonads almost always indicate the presence of testicular tissue and thus that the infant is a genetic male), and look for any other anatomic abnormalities. Ultrasonography is helpful in demonstrating the presence or absence of a uterus and can often locate the gonads. A rapid karyotype (such as fluorescence in situ hybridization of interphase nuclei for X and Y chromosomes) can quickly determine the genetic sex of the infant. These results are all likely to be available before the results of hormonal testing and together allow the clinical team to advise the parents as to the genetic sex of the infant and the anatomy of internal reproductive structures. Injection of contrast medium into the urogenital sinus of a virilized female demonstrates a vagina and uterus, and many surgeons utilize this information to formulate a plan for surgical management.

PRENATAL DIAGNOSIS

Prenatal diagnosis of 21-hydroxylase is possible late in the 1st trimester by analysis of DNA obtained by chorionic villus sampling or during the 2nd trimester by amniocentesis. This is usually done because the parents already have an affected child. Most often, the *CYP21* gene is analyzed for frequently occurring mutations; more rare mutations may be detected by DNA sequencing.

NEWBORN SCREENING

Because 21-hydroxylase deficiency is often undiagnosed in affected males until they have severe adrenal insufficiency, all states in the United States and many other countries have instituted newborn screening programs. These programs analyze **17-hydroxyprogesterone** levels in dried blood obtained by heelstick and absorbed on filter paper cards; the same cards are screened in parallel for other congenital conditions, such as hypothyroidism and phenylketonuria. Potentially affected infants are typically quickly recalled for additional testing (electrolytes and repeat 17-hydroxyprogesterone determination) at approximately 2 wk of age. Infants with salt-wasting disease often have abnormal electrolytes by this age but are usually not severely ill. Thus, screening programs are effective in preventing many cases of adrenal crisis in affected males. The nonclassic form of the disease is not reliably detected by newborn screening, but this is of little clinical significance because adrenal insufficiency does not occur in this type of 21-hydroxylase deficiency.

The main difficulty with current newborn screening programs is that to reliably detect all affected infants, the cutoff 17-hydroxyprogesterone levels for recalls are set so low that there is a very high frequency of false-positive results (i.e., the test has a low positive predictive value

of approximately 1%). This problem is worst in premature infants. Positive predictive value can be improved by using cutoff levels based on gestational age, and by utilizing more specific second-tier screening methods such as liquid chromatography followed by tandem mass spectrometry.

TREATMENT

Glucocorticoid Replacement

Cortisol deficiency is treated with glucocorticoids. Treatment also suppresses excessive production of androgens by the adrenal cortex and thus minimizes problems such as excessive growth and skeletal maturation and virilization. *This often requires larger glucocorticoid doses than are needed in other forms of adrenal insufficiency, typically 15-20 mg/m^2/24 hr of hydrocortisone daily administered orally in 3 divided doses.* Affected infants usually require dosing at the high end of this range. *Double or triple doses are indicated during* **periods of stress,** *such as infection or surgery.* Glucocorticoid treatment must be continued indefinitely in all patients with classic 21-hydroxylase deficiency but may not be necessary in patients with nonclassic disease unless signs of androgen excess are present. Therapy must be individualized. It is desirable to maintain linear growth along percentile lines; crossing to higher height percentiles may suggest undertreatment, whereas loss of height percentiles often indicates overtreatment with glucocorticoids. Overtreatment is also suggested by excessive weight gain. Pubertal development should be monitored by periodic examination, and skeletal maturation is evaluated by serial radiographs of the hand and wrist for bone age. Hormone levels, particularly 17-hydroxyprogesterone and androstenedione, should be measured early in the morning, before taking the morning medications, or at a consistent time in relation to medication dosing. In general, desirable 17- hydroxyprogesterone levels are in the high-normal range or several times normal; low-normal levels can usually be achieved only with excessive glucocorticoid doses.

Menarche occurs at the appropriate age in most girls in whom good control has been achieved; it may be delayed in girls with suboptimal control.

Children with simple virilizing disease, particularly males, are frequently not diagnosed until 3-7 yr of age, at which time skeletal maturation may be 5 yr or more in advance of chronological age. In some children, especially if the bone age is 12 yr or more, **spontaneous central (i.e., gonadotropin-dependent) puberty** may occur when treatment is instituted, because therapy with hydrocortisone suppresses production of adrenal androgens and thus stimulates release of pituitary gonadotropins if the appropriate level of hypothalamic maturation is present. *This form of superimposed true precocious puberty may be treated with a gonadotropin hormone–releasing hormone analog such as leuprolide* (see Chapter 562.1).

Males with 21-hydroxylase deficiency who have had inadequate corticosteroid therapy may develop **testicular adrenal rest tumors**, which usually regress with increased steroid dosage. Testicular MRI, ultrasonography, and color flow Doppler examination help define the character and extent of disease. Testis-sparing surgery for steroid-unresponsive tumors has been reported.

Mineralocorticoid Replacement

Patients with salt-wasting disease (i.e., aldosterone deficiency) require mineralocorticoid replacement with **fludrocortisone.** Infants may have very high mineralocorticoid requirements in the 1st few mo of life, usually 0.1-0.3 mg daily in 2 divided doses but occasionally up to 0.4 mg daily, and often require sodium supplementation (sodium chloride, 8 mmol/kg) in addition to the mineralocorticoid. Older infants and children are usually maintained with 0.05-0.1 mg daily of fludrocortisone. In some patients, simple virilizing disease may be easier to control with a low dose of fludrocortisone in addition to hydrocortisone even when these patients have normal aldosterone levels in the absence of mineralocorticoid replacement. Therapy is evaluated by monitoring of vital signs; tachycardia and hypertension are signs of overtreatment with mineralocorticoids. Serum electrolytes should be measured frequently in early infancy as therapy is adjusted. Plasma renin activity is a useful way to determine adequacy of therapy; it should be maintained in or near the normal range but not suppressed.

Additional approaches to improve outcome have been proposed but have not yet become the standard of care. These include an antiandrogen such as flutamide to block the effects of excessive androgen levels, and/or an aromatase inhibitor such as anastrozole, which blocks conversion of androgens to estrogen and thus retards skeletal maturation, a process that is sensitive to estrogens in both boys and girls. Aromatase inhibitors generally should not be used in pubertal girls because they will obviously retard normal puberty and may expose the ovaries to excessive levels of gonadotropins. Growth hormone, with or without luteinizing hormone–releasing hormone agonists to retard skeletal maturation, has been suggested to improve adult height.

Surgical Management of Ambiguous Genitals

Significantly virilized females usually undergo surgery between 2-6 mo of age. If there is severe clitoromegaly, the clitoris is reduced in size, with partial excision of the corporal bodies and preservation of the neurovascular bundle; however, moderate clitoromegaly may become much less noticeable even without surgery as the patient grows. Vaginoplasty and correction of the urogenital sinus usually are performed at the time of clitoral surgery; revision in adolescence is often necessary.

Risks and benefits of surgery should be fully discussed with parents of affected females. There is limited long-term follow-up of functional outcomes in patients who have undergone **modern** surgical procedures. It appears that female sexual dysfunction increases in frequency and severity in those with the most significant degrees of genital virilization and with the degree of enzymatic impairment (prenatal androgen exposure) caused by each patient's mutations (see Table 576-2). Sex assignment of infants with **disorders of sexual differentiation** (including CAH) is usually based on expected sexual functioning and fertility in adulthood with early surgical correction of the external genitals to conform with the sex assignment. Confused gender identity is not common with CAH; it occurs mostly in females with the salt-wasting form of the disease and the greatest degree of virilization.

Lay and medical opponents of genital surgery for other disorders of sexual differentiation state that it ignores any prenatally biased gender role predisposition from androgen exposure and precludes the patient from having any decision as to the patient's own preferred sexual identity and what surgical correction of the genitals should be performed. These individuals and groups say treatment should be aimed primarily at educating the patient, family, and others about the medical condition, its treatment, and how to deal with the intersex condition. They propose that surgery should be delayed until the patient decides on what, if any, correction should be performed. Severely virilized genotypic (XX) females raised as males have generally functioned well in the male gender as adults.

In adolescent and adult females with poorly controlled 21-hydroxylase deficiency (hirsutism, obesity, amenorrhea), bilateral laparoscopic adrenalectomy (with hormone replacement) may be an alternative to standard medical hormone replacement therapy, but patients treated in this way may be more susceptible to acute adrenal insufficiency if treatment is interrupted because the adrenal glands have been removed. Moreover, they may exhibit signs of elevated ACTH levels such as abnormal pigmentation.

Prenatal Treatment

Besides genetic counseling, the main goal of prenatal diagnosis is to facilitate appropriate prenatal treatment of affected females. Mothers with pregnancies at risk are given dexamethasone, a steroid that readily crosses the placenta, in an amount of 20 µg/kg prepregnancy maternal weight daily in 2 or 3 divided doses. This suppresses secretion of steroids by the fetal adrenal, including secretion of adrenal androgens. If started by 6 wk of gestation, it ameliorates virilization of the external

genitals in affected females. Chorionic villus biopsy is then performed to determine the sex and genotype of the fetus; therapy is continued only if the fetus is an affected female. DNA analysis of fetal cells isolated from maternal plasma for sex determination and *CYP21* gene analysis may permit earlier identification of the affected female fetus. Children exposed to this therapy have slightly lower birthweights. Effects on personality or cognition, such as increased shyness, have been suggested but not consistently observed. At present there is insufficient information to determine whether the long-term risks are acceptable, particularly in the males and unaffected females who derive no direct benefit from the treatment. Maternal side effects of prenatal treatment have included edema, excessive weight gain, hypertension, glucose intolerance, cushingoid facial features, and severe striae. Prenatal treatment is therefore carried out only under institutional protocols in some locales, but it is offered as an option outside the research setting by high-risk obstetricians in other communities.

576.2 Congenital Adrenal Hyperplasia Caused by 11β-Hydroxylase Deficiency

Perrin C. White

ETIOLOGY

Deficiency of 11β-hydroxylase is caused by a mutation in the *CYP11B1* gene located on chromosome 8q24. *CYP11B1* mediates 11-hydroxylation of 11-deoxycortisol to cortisol. Because 11-deoxycortisol is not converted to cortisol, levels of corticotropin are high. In consequence, precursors—particularly 11-deoxycortisol and deoxycorticosterone—accumulate and are shunted into androgen biosynthesis in the same manner as occurs in 21-hydroxylase deficiency. The adjacent *CYP11B2* gene encoding aldosterone synthase is generally unaffected in this disorder, so patients are able to synthesize aldosterone normally.

EPIDEMIOLOGY

11β-Hydroxylase deficiency accounts for approximately 5% of cases of adrenal hyperplasia; its incidence in the general population has been estimated as 1 in 250,000 to 1 in 100,000. The disorder occurs relatively frequently in Israeli Jews of North African origin (1 in 15,000-17,000 live births). In this ethnic group almost all alleles carry an Arg448 to His (R448H) mutation in *CYP11B1*, but many other mutations have been identified. This disorder presents in a classic, severe form and very rarely in a nonclassic, milder form.

CLINICAL MANIFESTATIONS

Although cortisol is not synthesized efficiently, aldosterone synthetic capacity is normal, and some corticosterone is synthesized from progesterone by the intact aldosterone synthase enzyme. Thus, it is unusual for patients to manifest signs of adrenal insufficiency such as hypotension, hypoglycemia, hyponatremia, and hyperkalemia. Approximately 65% of patients become **hypertensive,** although this can take several years to develop. Hypertension is probably a consequence of elevated levels of deoxycorticosterone, which has mineralocorticoid activity. Infants may transiently develop signs of mineralocorticoid deficiency after treatment with hydrocortisone is instituted. This is presumably from sudden suppression of deoxycorticosterone secretion in a patient with atrophy of the zona glomerulosa caused by chronic suppression of renin activity.

All signs and symptoms of androgen excess that are found in 21-hydroxylase deficiency may also occur in 11β-hydroxylase deficiency.

LABORATORY FINDINGS

Plasma levels of 11-deoxycortisol and deoxycorticosterone are elevated. Because deoxycorticosterone and metabolites have mineralocorticoid activity, plasma renin activity is suppressed. Consequently, aldosterone levels are low even though the ability to synthesize aldosterone is intact. Hypokalemic alkalosis occasionally occurs.

TREATMENT

Patients are treated with hydrocortisone in doses similar to those used for 21-hydroxylase deficiency. Mineralocorticoid replacement is sometimes transiently required in infancy but is rarely necessary otherwise. Hypertension often resolves with glucocorticoid treatment but may require additional therapy if it is of long standing. Calcium channel blockers may be beneficial under these circumstances.

Bibliography is available at Expert Consult.

576.3 Congenital Adrenal Hyperplasia Caused by 3β-Hydroxysteroid Dehydrogenase Deficiency

Perrin C. White

ETIOLOGY

Deficiency of 3β-hydroxysteroid dehydrogenase (3β-HSD) occurs in fewer than 2% of patients with adrenal hyperplasia. This enzyme is required for conversion of Δ5 steroids (pregnenolone, 17-hydroxypregnenolone, dehydroepiandrosterone [DHEA]) to Δ4 steroids (progesterone, 17-hydroxyprogesterone, and androstenedione). Thus, deficiency of the enzyme results in decreased synthesis of cortisol, aldosterone, and androstenedione but increased secretion of DHEA (see Fig. 574-1 in Chapter 574). The 3β-HSD isozyme expressed in the adrenal cortex and gonad is encoded by the *HSD3B2* gene located on chromosome 1p13.1. Over 30 mutations in the *HSD3B2* gene have been described in patients with 3β-HSD deficiency.

CLINICAL MANIFESTATIONS

Because cortisol and aldosterone are not synthesized in patients with the classic form of the disease, infants are prone to **salt-wasting crises.** Because androstenedione and testosterone are not synthesized, **boys are incompletely virilized.** Varying degrees of hypospadias may occur, with or without bifid scrotum or cryptorchidism. Because DHEA levels are elevated and this hormone is a weak androgen, girls are mildly virilized, with slight to moderate clitoral enlargement. Postnatally, continued excessive DHEA secretion can cause precocious adrenarche. During adolescence and adulthood, hirsutism, irregular menses, and polycystic ovarian disease occur in females. Males manifest variable degrees of hypogonadism, although appropriate male secondary sexual development may occur. A persistent defect of testicular 3β-HSD is demonstrated, however, by the high Δ5:Δ4 steroid ratio in testicular effluent.

LABORATORY FINDINGS

The hallmark of this disorder is the marked elevation of the Δ5 steroids (such as 17-hydroxypregnenolone and DHEA) preceding the enzymatic block. Patients may also have elevated levels of 17-hydroxyprogesterone because of the extraadrenal 3β-HSD activity that occurs in peripheral tissues; these patients may be mistaken for patients with 21-hydroxylase deficiency. The ratio of 17-hydroxypregnenolone:17-hydroxyprogesterone is markedly elevated in 3β-HSD deficiency, in contrast to the decreased ratio in 21-hydroxylase deficiency. Plasma renin activity is elevated in the salt-wasting form.

DIFFERENTIAL DIAGNOSIS

It is not unusual for children with premature adrenarche, or women with signs of androgen excess, to have mild to moderate elevations in DHEA levels. It has been suggested that such individuals have "nonclassic 3β-HSD deficiency." Mutations in the *HSD3B2* gene are usually not found in such individuals, and a nonclassic form of this deficiency must actually be quite rare. The activity of 3β-HSD in the adrenal zonae

fasciculata and reticularis, relative to CYP17 (17-hydroxylase/17,20-lyase) activity, normally decreases during adrenarche to facilitate DHEA synthesis, and so modest elevations in DHEA in preteenage children or women usually represent a normal variant.

TREATMENT

Patients require glucocorticoid and mineralocorticoid replacement with hydrocortisone and fludrocortisone, respectively, as in 21-hydroxylase deficiency. Incompletely virilized genetic males in whom a male sex of rearing is contemplated may benefit from several injections of 25 mg every 4 wk of a depot form of testosterone early in infancy to increase the size of the phallus. They may also require testosterone replacement at puberty.

Bibliography is available at Expert Consult.

576.4 Congenital Adrenal Hyperplasia Caused by 17-Hydroxylase Deficiency

Perrin C. White

ETIOLOGY

Less than 1% of CAH cases are caused by 17-hydroxylase deficiency, but the condition is apparently more common in Brazil and China. A single polypeptide, CYP17, catalyzes 2 distinct reactions: 17-hydroxylation of pregnenolone and progesterone to 17-hydroxypregnenolone and 17-hydroxyprogesterone, respectively, and the 17,20-lyase reaction mediating conversion of 17-hydroxypregnenolone to DHEA and, to a lesser extent, 17-hydroxyprogesterone to Δ4-androstenedione. DHEA and androstenedione are steroid precursors of testosterone and estrogen (see Fig. 574-1 in Chapter 574). The enzyme is expressed in both the adrenal cortex and the gonads and is encoded by a gene on chromosome 10q24.3. Most mutations affect both the hydroxylase and lyase activities, but rare mutations can affect either activity alone.

Mutations in genes other than *CYP17* can have the same phenotype as 17,20-lyase deficiency (i.e., deficient androgen synthesis with normal cortisol synthesis). These include an accessory electron transfer protein, cytochrome b_5, and mutations in 2 aldo-keto reductases, AKR1C2 and AKR1C4. These AKR1C isozymes normally catalyze 3α-hydroxysteroid dehydrogenase activity, which allows synthesis of the potent androgen dihydrotestosterone through an alternative "backdoor" biosynthetic pathway that does not include testosterone as an intermediate.

CLINICAL MANIFESTATIONS AND LABORATORY FINDINGS

Patients with 17-hydroxylase deficiency cannot synthesize cortisol, but their ability to synthesize corticosterone is intact. Because corticosterone is an active glucocorticoid, patients do not develop adrenal insufficiency. Deoxycorticosterone, the immediate precursor of corticosterone, is synthesized in excess. This can cause **hypertension, hypokalemia,** and suppression of renin and aldosterone secretion, as occurs in 11β-hydroxylase deficiency. In contrast to 11β-hydroxylase deficiency, patients with 17-hydroxylase deficiency are unable to synthesize sex hormones. Affected **males are incompletely virilized** and present as phenotypic females (but gonads are usually palpable in the inguinal region or the labia) or with sexual ambiguity. Affected females usually present with **failure of sexual development** at the expected time of **puberty.** 17-Hydroxylase deficiency in females must be considered in the differential diagnosis of primary hypogonadism (see Chapter 586). Levels of deoxycorticosterone are elevated and renin and aldosterone are consequently suppressed. Cortisol and sex steroids are unresponsive to stimulation with ACTH and human chorionic gonadotropin, respectively.

Patients with isolated 17,20-lyase deficiency have deficient androgen synthesis with normal cortisol synthesis, and therefore do not become hypertensive.

TREATMENT

Patients with 17-hydroxylase deficiency require cortisol replacement to suppress secretion of deoxycorticosterone and thus control hypertension. Additional antihypertensive medication may be required. Females require estrogen replacement at puberty. Genetic males may require either estrogen or androgen supplementation depending on the sex of rearing. Because of the possibility of malignant transformation of abdominal testes with androgen insensitivity syndrome (see Chapter 588.2), genetic males with severe 17-hydroxylase deficiency being reared as females require gonadectomy at or before adolescence.

Bibliography is available at Expert Consult.

576.5 Lipoid Adrenal Hyperplasia

Perrin C. White

ETIOLOGY

Lipoid adrenal hyperplasia is a rare disorder, most frequently found in Japanese persons. Patients with this disorder exhibit marked accumulation of cholesterol and lipids in the adrenal cortex and gonads, associated with severe impairment of all steroidogenesis. Lipoid adrenal hyperplasia is usually caused by mutations in the gene for steroidogenic acute regulatory protein (StAR), a mitochondrial protein that promotes the movement of cholesterol from the outer to the inner mitochondrial membrane. However, mutations in the *CYP11A1* gene (which encodes the cholesterol side chain cleavage enzyme) have been reported in several patients.

Some cholesterol is able to enter mitochondria even in the absence of StAR, so it might be supposed that this disorder would not completely impair steroid biosynthesis. However, the accumulation of cholesterol in the cytoplasm is cytotoxic, eventually leading to death of all steroidogenic cells in which StAR is normally expressed. This occurs prenatally in the adrenals and testes. The ovaries do not normally synthesize steroids until puberty, so cholesterol does not accumulate and the ovaries can retain the capacity to synthesize estrogens until adolescence.

Although estrogens synthesized by the placenta are required to maintain pregnancy, the placenta does not require StAR for steroid biosynthesis. Thus, mutations of StAR are not prenatally lethal.

CLINICAL MANIFESTATIONS

Patients with lipoid adrenal hyperplasia are usually unable to synthesize any adrenal steroids. Thus, affected infants are likely to be confused with those with adrenal hypoplasia congenita. Salt-losing manifestations are typical, and many infants die in early infancy. Genetic males are unable to synthesize androgens and thus are **phenotypically female** but with gonads palpable in the labia majora or inguinal areas. Genetic females appear normal at birth and may undergo feminization at puberty with menstrual bleeding. They too, progress to hypergonadotropic hypogonadism when accumulated cholesterol kills granulosa (i.e., steroid synthesizing) cells in the ovary.

LABORATORY FINDINGS

Adrenal and gonadal steroid hormone levels are low in lipoid adrenal hyperplasia, with a decreased or absent response to stimulation (ACTH, human chorionic gonadotropin). Plasma renin levels are increased.

Imaging studies of the adrenal gland demonstrating massive adrenal enlargement in the newborn help establish the diagnosis of lipoid adrenal hyperplasia.

TREATMENT

Patients require glucocorticoid and mineralocorticoid replacement. Genetic males are usually assigned a female sex of rearing; thus both genetic males and females require estrogen replacement at the expected age of puberty.

576.6 Deficiency of P450 Oxidoreductase (Antley-Bixler Syndrome)

Perrin C. White

ETIOLOGY, PATHOGENESIS, AND CLINICAL MANIFESTATIONS

P450 oxidoreductase (POR, gene located on chromosome 7q11.3) is required for the activity of all microsomal cytochrome P450 enzymes (see Chapter 574) including the adrenal enzymes CYP17 and CYP21. Thus, complete POR deficiency abolishes all microsomal P450 activity. This is embryonically lethal in mice and presumably in humans as well. Patients with mutations that decrease but do not abolish POR activity have partial deficiencies of 17-hydroxylase and 21-hydroxylase activities in the adrenals. A single recurrent mutation, A287P (alanine-287 to proline) is found on approximately 40% of alleles.

Deficiency of 17-hydroxylase leads to incomplete masculinization in males; 21-hydroxylase deficiency may lead to virilization in females. Additionally, aromatase *(CYP19)* activity in the placenta is decreased, leading to unopposed action of androgens produced by the fetal adrenal. This exacerbates virilization of female fetuses and may **virilize the mother** of an affected fetus as well. Although it is puzzling that affected females could be virilized despite a partial deficiency in *CYP17* (which is required for androgen biosynthesis), an alternative ("back-door") biosynthetic pathway is utilized in which 17-hydroxyprogesterone is converted to 5α-pregnane-3α,17α-diol-20-one, a metabolite that is a much better substrate for the 17,20-lyase activity of *CYP17* than the usual substrate, 17-hydroxypregnenolone (see Chapter 574). The metabolite is then converted in several enzymatic steps to dihydrotestosterone, a potent androgen.

Because many other P450 enzymes are affected, patients often (but not invariably) have other congenital anomalies collectively referred to as **Antley-Bixler syndrome.** These include craniosynostosis; brachycephaly; frontal bossing; severe midface hypoplasia with proptosis and choanal stenosis or atresia; humeroradial synostosis; medial bowing of ulnas; long, slender fingers with camptodactyly; narrow iliac wings; anterior bowing of femurs; and malformations of the heart and kidneys. Studies of mutant mice suggest that the metabolic defects responsible for these anomalies include defective metabolism of retinoic acid, leading to elevated levels of this teratogenic compound, and deficient biosynthesis of cholesterol.

EPIDEMIOLOGY

The prevalence is not known with certainty. It must be rare compared with 21-hydroxylase deficiency but might occur at similar frequencies to the other forms of CAH.

LABORATORY FINDINGS

Serum steroids that are not 17- or 21-hydroxylated are most increased, including pregnenolone and progesterone. 17-Hydroxy, 21-deoxysteroids are also increased, including 17-hydroxypregnenolone, 17-hydroxyprogesterone, and 21-deoxycortisol. Urinary steroid metabolites may be determined by quantitative mass spectrometry. Metabolites excreted at increased levels include pregnanediol, pregnanetriol, pregnanetriolone, and corticosterone metabolites. Urinary cortisol metabolites are decreased. Genetic analysis demonstrates mutations in the *POR* gene.

DIFFERENTIAL DIAGNOSIS

This disorder must be distinguished from other forms of CAH, particularly 21-hydroxylase deficiency in females, which is far more common and has similar laboratory findings. Suspicion for *POR* deficiency may be raised if the mother is virilized or if the associated abnormalities of Antley-Bixler syndrome are present. Conversely, virilization of both the mother and her daughter can result from a luteoma of pregnancy, but in this case postnatal abnormalities of corticosteroid biosynthesis should not be observed. Antley-Bixler syndrome may also occur without abnormalities of steroid hormone biosynthesis, resulting from mutations in the fibroblast growth factor receptor FGFR2.

576.7 Aldosterone Synthase Deficiency

Perrin C. White

ETIOLOGY

This is a rare autosomal recessive disorder in which conversion of corticosterone to aldosterone is impaired; a group of Iranian Jewish patients has been the most thoroughly studied. The majority of cases result from mutations in the *CYP11B2* gene coding for aldosterone synthase; however, linkage to *CYP11B2* has been excluded in other kindreds. When not caused by *CYP11B2* mutations, the disorder has been termed *familial hyperreninemic hypoaldosteronism type 2;* the causative gene or genes have not yet been identified.

Aldosterone synthase mediates the 3 final steps in the synthesis of aldosterone from deoxycorticosterone (11β-hydroxylation, 18-hydroxylation, and 18-oxidation). Although 11β-hydroxylation is required to convert deoxycorticosterone to corticosterone, this conversion can also be catalyzed by the related enzyme, CYP11B1, located in the fasciculata, which is unaffected in this disorder. For the same reason, these patients have normal cortisol biosynthesis.

The disease has been classified into 2 types, termed *corticosterone methyloxidase deficiency types I and II.* They differ only in levels of the immediate precursor of aldosterone, 18-hydroxycorticosterone; levels are low in type I deficiency and elevated in type II deficiency. These differences do not correspond in a simple way to particular mutations and are of limited clinical importance.

CLINICAL MANIFESTATIONS

Infants with aldosterone synthase deficiency may have severe electrolyte abnormalities with **hyponatremia, hyperkalemia,** and **metabolic acidosis.** Because cortisol synthesis is unaffected, infants rarely become as ill as untreated infants with salt-losing forms of CAH such as 21-hydroxylase deficiency. Thus, some infants escape diagnosis. Later in infancy or in early childhood they may exhibit failure to thrive and poor growth. Adults often are asymptomatic, although they may develop electrolyte abnormalities when depleted of sodium through procedures such as bowel preparation for a barium enema.

LABORATORY FINDINGS

Infants have elevated plasma renin activity. Aldosterone levels are decreased; they may be at the lower end of the normal range but are always inappropriately low for the degree of hyperkalemia or hyperreninemia. Corticosterone levels are often elevated.

Some, but not all, patients have marked elevation of 18-hydroxycorticosterone; however, low levels of this steroid do not exclude the diagnosis. In those kindreds in which 18-hydroxycorticosterone levels are elevated in affected individuals, this biochemical abnormality persists in adults even when they have no electrolyte abnormalities.

DIFFERENTIAL DIAGNOSIS

It is important to distinguish aldosterone synthase deficiency from primary adrenal insufficiency in which both cortisol and aldosterone are affected (including salt-wasting forms of CAH) because the latter condition is usually associated with a much greater risk of shock and hyponatremia. This becomes apparent after the appropriate laboratory studies. Adrenal hypoplasia congenita may initially present with aldosterone deficiency; all male infants with apparently isolated aldosterone deficiency should be carefully monitored for subsequent development of cortisol deficiency. **Pseudohypoaldosteronism** (see Chapter 575.4) may have similar electrolyte abnormalities and

hyperreninemia, but aldosterone levels are high, and this condition usually does not respond to fludrocortisone treatment.

TREATMENT

Treatment consists of giving enough fludrocortisone (0.05-0.3 mg daily) or sodium chloride, or both, to return plasma renin levels to normal. With increasing age, salt-losing signs usually improve and drug therapy can often be discontinued.

576.8 Glucocorticoid-Suppressible Hyperaldosteronism

Perrin C. White

ETIOLOGY

Glucocorticoid-suppressible hyperaldosteronism (glucocorticoid-remediable aldosteronism, familial hyperaldosteronism type I) is an autosomal dominant form of **low-renin hypertension** in which hyperaldosteronism is rapidly suppressed by glucocorticoid administration. This unusual effect of glucocorticoids suggests that aldosterone secretion in this disorder is regulated by ACTH instead of by the renin–angiotensin system. In addition to abnormally regulated secretion of aldosterone, there is marked overproduction of 18-hydroxycortisol and 18-oxocortisol. The synthesis of these steroids requires both 17-hydroxylase (CYP17) activity, which is expressed only in the zona fasciculata, and aldosterone synthase (CYP11B2) activity, which is normally expressed only in the zona glomerulosa. Together, these features imply that aldosterone synthase is being expressed in a manner similar to the closely related enzyme steroid 11-hydroxylase *(CYP11B1).* The disorder is caused by unequal meiotic crossing-over events between the *CYP11B1* and *CYP11B2* genes, which are closely linked on chromosome 8q24. An additional "hybrid" gene is produced, having regulatory sequences of *CYP11B1* juxtaposed with coding sequences of *CYP11B2.* This results in the inappropriate expression of a *CYP11B2*-like enzyme with aldosterone synthase activity in the adrenal fasciculata.

CLINICAL MANIFESTATIONS

Some affected children have no symptoms, the diagnosis being established after incidental discovery of moderate hypertension, typically approximately 30 mm Hg higher than unaffected family members of the same age. Others have more symptomatic hypertension with headache, dizziness, and visual disturbances. A strong family history of early-onset hypertension or early strokes may alert the clinician to the diagnosis. Some patients have chronic hypokalemia, but this is not a consistent finding and is usually mild.

LABORATORY FINDINGS

Patients have elevated plasma and urine levels of aldosterone and suppressed plasma renin activity. Hypokalemia is not consistently present. Urinary and plasma levels of 18-oxocortisol and 18-hydroxycortisol are markedly increased. The hybrid *CYP11B1/CYP11B2* gene can be readily detected by molecular genetic methods.

DIFFERENTIAL DIAGNOSIS

This condition should be distinguished from primary aldosteronism based on bilateral hyperplasia or an aldosterone-producing adenoma (see Chapter 578). Most cases of primary aldosteronism are sporadic, although several affected kindreds have been reported. Patients with primary aldosteronism may also have elevated levels of 18-hydroxycortisol and 18-oxocortisol, and these biochemical tests should be used cautiously to distinguish primary and glucocorticoid-suppressible aldosteronism. A therapeutic trial of dexamethasone may be helpful if aldosterone secretion is suppressed, and genetic testing should identify the hybrid gene of glucocorticoid-suppressible hyperaldosteronism if it is present.

TREATMENT

Glucocorticoid-suppressible hyperaldosteronism is managed by daily administration of a glucocorticoid, usually dexamethasone, 25 µg/kg/day in divided doses. If necessary, effects of aldosterone can be blocked with a potassium-sparing diuretic such as spironolactone, eplerenone, or amiloride. Hypertension resolves in patients in whom the hypertension is not severe or of long standing. If hypertension is long standing, additional antihypertensive medication may be required, such as a calcium channel blocker.

GENETIC COUNSELING

Because of the autosomal dominant mode of inheritance, at-risk family members should be investigated for this easily treated cause of hypertension.

Chapter 577

Cushing Syndrome

Perrin C. White

Cushing syndrome is the result of abnormally high blood levels of cortisol or other glucocorticoids. This can be iatrogenic or the result of endogenous cortisol secretion, a result of either an adrenal tumor or of hypersecretion of corticotropin (adrenocorticotropic hormone [ACTH]) by the pituitary (Cushing disease) or by a tumor (Table 577-1).

ETIOLOGY

The most common cause of Cushing syndrome is prolonged exogenous administration of glucocorticoid hormones, especially at the high doses used to treat lymphoproliferative disorders. This rarely represents a diagnostic challenge, but management of hyperglycemia, hypertension, weight gain, linear growth retardation, and osteoporosis often complicates therapy with corticosteroids.

Endogenous Cushing syndrome is most often caused in infants by a functioning adrenocortical tumor (see Chapter 579). Patients with these tumors often exhibit signs of hypercortisolism along with signs of hypersecretion of other steroids such as androgens, estrogens, and aldosterone.

Although extremely rare in infants, the most common etiology of endogenous Cushing syndrome in children older than 7 yr of age is **Cushing disease,** in which excessive ACTH secreted by a pituitary adenoma causes bilateral adrenal hyperplasia. Such adenomas are often too small to detect by imaging techniques and are termed microadenomas. They consist principally of chromophobe cells and frequently show positive immunostaining for ACTH and its precursor, proopiomelanocortin. Whereas the vast majority of such tumors are sporadic, a small number occur in kindreds with familial isolated pituitary adenoma syndrome. This syndrome, which is caused by mutations in the aryl hydrocarbon receptor interacting protein *(AIP)* gene, accounts for perhaps 2% of pituitary adenomas, but more commonly tumors with *AIP* mutations secrete growth hormone or prolactin, and only rarely do they secrete ACTH. Similarly, multiple endocrine neoplasia type 1 (MEN1) patients, who by definition have mutations in the MEN1 (menin) gene, may develop pituitary tumors, but these are typically prolactinomas.

ACTH-dependent Cushing syndrome may also result from ectopic production of ACTH, although this is uncommon in children. Ectopic

Table 577-1	Etiologic Classification of Adrenocortical Hyperfunction
EXCESS ANDROGEN Congenital adrenal hyperplasia 21-Hydroxylase (P450c21) deficiency 11β-Hydroxylase (P450c11) deficiency 3β-Hydroxysteroid dehydrogenase defect (deficiency or dysregulation) Tumor

EXCESS MINERALOCORTICOID Primary hyperaldosteronism Aldosterone-secreting adenoma Bilateral micronodular adrenocortical hyperplasia Glucocorticoid-suppressible aldosteronism Tumor Deoxycorticosterone excess Congenital adrenal hyperplasia 11β-Hydroxylase (P450c11) 17α-Hydroxylase (P450c17) Tumor Apparent mineralocorticoid excess (deficiency of 11β-hydroxysteroid dehydrogenase type 2)	
EXCESS ESTROGEN Tumor	

ACTH secretion in children is associated with islet cell carcinoma of the pancreas, neuroblastoma or ganglioneuroblastoma, hemangiopericytoma, Wilms tumor, and thymic carcinoid. Hypertension is more common in the ectopic ACTH syndrome than in other forms of Cushing syndrome, because very high cortisol levels may overwhelm 11β-hydroxysteroid dehydrogenase in the kidney (see Chapter 575) and thus have an enhanced mineralocorticoid (salt-retaining) effect.

Several syndromes are associated with the development of multiple autonomously hyperfunctioning nodules of adrenocortical tissue, rather than single adenomas or carcinomas (which are discussed in Chapter 579). **Primary pigmented nodular adrenocortical disease** (PPNAD) is a distinctive form of ACTH-independent Cushing syndrome. It may occur as an isolated event or, more commonly, as a familial disorder with other manifestations. The adrenal glands are small and have characteristic multiple, small (<4 mm in diameter), pigmented (black) nodules containing large cells with cytoplasm and lipofuscin; there is cortical atrophy between the nodules. This adrenal disorder occurs as a component of **Carney complex,** an autosomal dominant disorder also consisting of centrofacial lentigines and blue nevi; cardiac and cutaneous myxomas; pituitary, thyroid, and testicular tumors; and pigmented melanotic schwannomas. Carney complex is inherited in an autosomal dominant manner, although sporadic cases occur. Genetic loci for Carney complex have been mapped to the gene for the type 1α regulatory subunit of protein kinase A (PRKAR1A) on chromosome 17q22-24 and less frequently to chromosome 2p16. Patients with Carney complex and PRKAR1A mutations generally develop PPNAD as adults, and those with the disorder mapping to chromosome 2 (and most sporadic cases) develop PPNAD less frequently and later. Conversely, children presenting with PPNAD as an isolated finding rarely have mutations in PRKAR1A, or subsequently develop other manifestations of Carney complex. Some patients with isolated PPNAD have mutations in the *PDE8B* or *PDE11A* genes encoding different phosphodiesterase isozymes.

ACTH-independent Cushing syndrome with nodular hyperplasia and adenoma formation occurs rarely in cases of **McCune-Albright syndrome,** with symptoms beginning in infancy or childhood. McCune-Albright syndrome is caused by a somatic mutation of the *GNAS* gene encoding the G protein, $G_s\alpha$, through which the ACTH receptor (MCR2) normally signals. This results in inhibition of guanosine triphosphatase activity and constitutive activation of adenylate cyclase, thus increasing levels of cyclic adenosine monophosphate. When the mutation is present in adrenal tissue, cortisol and cell division are stimulated independently of ACTH. Other tissues in which activating mutations may occur are bone (producing fibrous dysplasia), gonads, thyroid, and pituitary. Clinical manifestations depend on which tissues are affected.

Thus the genes causing nodular adrenocortical hyperplasia that have been identified thus far all produce overactivity of the ACTH signaling pathway either by constitutively activating $G_s\alpha$ (McCune-Albright syndrome), by reducing the breakdown of cyclic adenosine monophosphate and thus increasing its intracellular levels (mutations of *PDE8B* or *PDE11A*), or by disrupting the regulation of the cyclic adenosine monophosphate–dependent enzyme, protein kinase A (PRKAR1A mutations).

Additionally, adrenocortical lesions including diffuse hyperplasia, nodular hyperplasia, adenoma, and rarely carcinoma may occur as part of the MEN1 syndrome (see Chapter 573), an autosomal dominant disorder, in which there is homozygous inactivation of the menin **(MEN1)** tumor-suppressor gene on chromosome 11q13.

CLINICAL MANIFESTATIONS

Signs of Cushing syndrome have been recognized in infants younger than 1 yr of age. The disorder appears to be more severe and the clinical findings more flagrant in infants than in older children. The face is rounded, with prominent cheeks and a flushed appearance (moon facies). Generalized obesity is common in younger children. In children with adrenal tumors, signs of abnormal masculinization occur frequently; accordingly, there may be hirsutism on the face and trunk, pubic hair, acne, deepening of the voice, and enlargement of the clitoris in girls. Growth is impaired, with length falling below the 3rd percentile, except when significant virilization produces normal or even accelerated growth. Hypertension is common and may occasionally lead to heart failure. An increased susceptibility to infection may also lead to sepsis.

In older children, in addition to obesity, short stature is a common presenting feature. Gradual onset of obesity and deceleration or cessation of growth may be the only early manifestations. Older children most often have more severe obesity of the face and trunk compared with the extremities. Purplish striae on the hips, abdomen, and thighs are common. Pubertal development may be delayed, or amenorrhea may occur in girls past menarche. Weakness, headache, and emotional lability may be prominent. Hypertension and hyperglycemia usually occur; hyperglycemia may progress to frank diabetes. Osteoporosis is common and may cause pathologic fractures.

LABORATORY FINDINGS

Cortisol levels in blood are normally highest at 8 AM and decrease to less than 50% by midnight except in infants and young children in whom a diurnal rhythm is not always established. In patients with Cushing syndrome this circadian rhythm is lost; midnight cortisol levels >4.4 µg/dL strongly suggest the diagnosis. It is difficult to obtain diurnal blood samples as part of an outpatient evaluation, but cortisol can be measured in saliva samples, which can be obtained at home at the appropriate times of day. Elevated nighttime salivary cortisol levels raise suspicion for Cushing syndrome.

Urinary excretion of free cortisol is increased. This is best measured in a 24 hr urine sample and is expressed as a ratio of micrograms of cortisol excreted per gram of creatinine. This ratio is independent of body size and completeness of the urine collection.

A single-dose dexamethasone suppression test is often helpful; a dose of 25-30 μg/kg (maximum: 2 mg) given at 11 PM results in a plasma cortisol level of less than 5 μg/dL at 8 AM the next morning in normal individuals but not in patients with Cushing syndrome. It is prudent to measure the dexamethasone level in the same blood sample to ensure adequacy of dosing.

A glucose tolerance test is often abnormal but is of no diagnostic utility. Levels of serum electrolytes are usually normal, but potassium may be decreased, especially in patients with tumors that secrete ACTH ectopically.

After the diagnosis of Cushing syndrome has been established, it is necessary to determine whether it is caused by a pituitary adenoma, an ectopic ACTH-secreting tumor, or a cortisol-secreting adrenal tumor. ACTH concentrations are usually suppressed in patients with cortisol-secreting tumors and are very high in patients with ectopic ACTH-secreting tumors but may be normal in patients with ACTH-secreting pituitary adenomas. After an intravenous bolus of corticotropin-releasing hormone, patients with ACTH-dependent Cushing syndrome have an exaggerated ACTH and cortisol response, whereas those with adrenal tumors show no increase in ACTH and cortisol. The 2-step dexamethasone suppression test consists of administration of dexamethasone, 30 and 120 μg/kg/24 hr in 4 divided doses, on consecutive days. In children with pituitary/Cushing syndrome, the larger dose, but not the smaller dose, suppresses serum levels of cortisol. Typically, patients with ACTH-independent Cushing syndrome do not show suppressed cortisol levels with dexamethasone.

CT detects virtually all adrenal tumors larger than 1.5 cm in diameter. MRI may detect ACTH-secreting pituitary adenomas, but many are too small to be seen; the addition of gadolinium contrast increases the sensitivity of detection. Bilateral inferior petrosal blood sampling to measure concentrations of ACTH before and after corticotropin-releasing hormone administration may be required to localize the tumor when a pituitary adenoma is not visualized; this is not routinely available in many centers, and moreover may be of decreased specificity in children.

DIFFERENTIAL DIAGNOSIS

Cushing syndrome is frequently suspected in children with obesity, particularly when striae and hypertension are present. Children with simple obesity are usually tall, whereas those with Cushing syndrome are short or have a decelerating growth rate. Although urinary excretion of cortisol is often elevated in simple obesity, salivary nighttime levels of cortisol are usually normal and cortisol secretion is suppressed by oral administration of low doses of dexamethasone.

Elevated levels of cortisol and ACTH without clinical evidence of Cushing syndrome occur in patients with generalized glucocorticoid resistance (see Chapter 575.4). Affected patients may be asymptomatic or exhibit hypertension, hypokalemia, and precocious pseudopuberty; these manifestations are caused by increased mineralocorticoid and adrenal androgen secretion in response to elevated ACTH levels. Mutations in the glucocorticoid receptor have been identified.

TREATMENT

Transsphenoidal pituitary microsurgery is the treatment of choice in pituitary Cushing disease in children. The overall success rate with follow-up of less than 10 yr is 60-80%. Low postoperative serum or urinary cortisol concentrations predict long-term remission in the majority of cases. Relapses are treated with reoperation or pituitary irradiation.

Cyproheptadine, a centrally acting serotonin antagonist that blocks ACTH release, has been used to treat Cushing disease in adults; remissions are usually not sustained after discontinuation of therapy. This agent is rarely used in children. Inhibitors of adrenal steroidogenesis (metyrapone, ketoconazole, aminoglutethimide, etomidate) have been used preoperatively to normalize circulating cortisol levels and reduce perioperative morbidity and mortality. Mifepristone, a glucocorticoid receptor antagonist, has been used in a limited number of cases.

Pasireotide, a somatostatin analog, can inhibit ACTH secretion, and is approved for use in adults with persistent disease after surgery or in whom surgery is contraindicated.

If a pituitary adenoma does not respond to treatment or if ACTH is secreted by an ectopic metastatic tumor, the adrenal glands may need to be removed. This can often be accomplished laparoscopically. Adrenalectomy may lead to increased ACTH secretion by an unresected pituitary adenoma, evidenced mainly by marked hyperpigmentation; this condition is termed **Nelson syndrome.**

Management of patients undergoing adrenalectomy requires adequate preoperative and postoperative replacement therapy with a corticosteroid. Tumors that produce corticosteroids usually lead to atrophy of the normal adrenal tissue, and replacement with cortisol (10 mg/m^2/24 hr in 3 divided doses after the immediate postoperative period) is required until there is recovery of the hypothalamic-pituitary-adrenal axis. Postoperative complications may include sepsis, pancreatitis, thrombosis, poor wound healing, and sudden collapse, particularly in infants with Cushing syndrome. Substantial catch-up growth, pubertal progress, and increased bone density occur, but bone density remains abnormal and adult height is often compromised. The management of adrenocortical tumors is discussed in Chapter 579.

Chapter 578

Primary Aldosteronism

Perrin C. White

Primary aldosteronism encompasses disorders caused by excessive aldosterone secretion independent of the renin–angiotensin system. These disorders are characterized by **hypertension, hypokalemia,** and suppression of the renin–angiotensin system.

ETIOLOGY

Aldosterone-secreting adenomas are unilateral and have been reported in children as young as 3.5 yr of age; they mainly affect girls. Adrenocortical tumors are discussed further in Chapter 579. Bilateral micronodular adrenocortical hyperplasia tends to occur in older children and is more frequent in males. Primary aldosteronism due to unilateral adrenal hyperplasia may also occur. Glucocorticoid-suppressible hyperaldosteronism is discussed in Chapter 576.8.

EPIDEMIOLOGY

These conditions are thought to be rare in children, but they may account for 5-10% of cases of hypertension in adults. Although usually sporadic, kindreds with several affected members have been reported. Genetic linkage to chromosome 7p22 has been identified in some of these kindreds, but the involved gene has not yet been identified. Mutations in the *KCNJ5* gene on chromosome 11q24 have been identified in several kindreds; these mutations (G151R and G151E) altered channel selectivity, producing increased Na^+ conductance and membrane depolarization, which increases aldosterone production and proliferation of adrenal glomerulosa cells. Moreover, such mutations have been identified in a subset of sporadic aldosterone-producing adenomas.

CLINICAL MANIFESTATIONS

Some affected children have no symptoms, the diagnosis being established after incidental discovery of moderate hypertension. Others have severe hypertension (up to 240/150 mm Hg), with headache, dizziness, and visual disturbances. Chronic hypokalemia, if present, may lead to polyuria, nocturia, enuresis, and polydipsia. Muscle weakness and discomfort, tetany, intermittent paralysis, fatigue, and growth failure affect children with severe hypokalemia.

LABORATORY FINDINGS

Hypokalemia occurs frequently. Serum pH and the carbon dioxide and sodium concentrations may be elevated and the serum chloride and magnesium levels decreased. Serum levels of calcium are normal, even in children who manifest tetany. The urine is neutral or alkaline, and urinary potassium excretion is high. Plasma levels of aldosterone may be normal or elevated. Aldosterone concentrations in 24 hr urine collections are always increased. Plasma levels of renin are persistently low.

The diagnostic test of choice for primary aldosteronism is controversial. Both renin and aldosterone levels may vary by time of day, posture, and sodium intake, making it difficult to establish consistent reference ranges. It is desirable to establish a consistent sampling protocol, for example, at midmorning after the patient has been sitting for 15 min. If possible, antihypertensive drugs or other medications that can affect aldosterone or renin secretion should be avoided for several weeks prior to testing, including diuretics, β-blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, clonidine, and nonsteroidal antiinflammatory agents. Patients taking these agents may need to be changed to α-adrenergic blockers or calcium channel blockers that have smaller effects on the biochemical measurements. The ratio of plasma aldosterone concentration to renin activity is always high, and this represents a cost-effective screening test for primary aldosteronism. Aldosterone does not decrease with administration of saline solution or fludrocortisone, and renin does not respond to salt and fluid restriction. Urinary and plasma levels of 18-oxocortisol and 18-hydroxycortisol may be increased but not to the extent seen in glucocorticoid-suppressible hyperaldosteronism.

DIFFERENTIAL DIAGNOSIS

Primary aldosteronism should be distinguished from glucocorticoid-suppressible hyperaldosteronism (see Chapter 576.8), which is specifically treated with glucocorticoids. An autosomal dominant pattern of inheritance should raise suspicion for the latter disorder. Glucocorticoid-suppressible hyperaldosteronism is diagnosed by dexamethasone suppression tests or by specific genetic testing. More generally, primary aldosteronism should be distinguished from other forms of hypertension by means of the testing previously discussed.

TREATMENT

The treatment of an aldosterone-producing adenoma is surgical removal. This is performed primarily by laparotomy and adrenalectomy; successful enucleation of aldosterone-producing adenomas, as well as laparoscopic adrenalectomy, has been reported. *Hyperaldosteronism caused by bilateral adrenal hyperplasia is treated with the mineralocorticoid antagonists spironolactone (1-3 mg/kg/day to a maximum of 100 mg/day) or eplerenone (25-100 mg/day in 2 divided doses),* often normalizing blood pressure and serum potassium levels. There is greater experience with spironolactone, but this agent has antiandrogenic properties that may be unacceptable in pubertal males. Eplerenone is a more specific antimineralocorticoid that is safe in children, but there is little specific experience with primary aldosteronism in the pediatric age group. As an alternative, an epithelial sodium channel blocker, such as amiloride, may be used, with other antihypertensive agents added as necessary. In patients whose condition cannot be controlled medically, unilateral adrenalectomy may be considered.

Chapter 579

Adrenocortical Tumors

Perrin C. White

EPIDEMIOLOGY

Adrenocortical tumors are rare in childhood, with an incidence of 0.3-0.5 cases per 1 million child-years. They occur in all age groups but most commonly in children younger than 6 yr of age, and are more frequent (1.6-fold) in girls. In 2-10% of cases, the tumors are bilateral. Almost half of childhood adrenocortical tumors are carcinomas.

Symptoms of endocrine hyperfunction are present in 80-90% of children with adrenal tumors (see Table 577-1 in Chapter 577). Tumors that secrete cortisol and aldosterone are also discussed in Chapters 577 and 578, respectively. Tumors may be associated with hemihypertrophy, usually occurring during the 1st few yr of life. They are also associated with other congenital defects, particularly genitourinary tract and central nervous system abnormalities and hamartomatous defects.

ETIOLOGY

The incidence of adrenocortical tumors is increased in several familial cancer syndromes resulting from abnormalities in genes that encode transcription factors implicated in cell proliferation, differentiation, senescence, apoptosis, and genomic instability. These include tumor protein 53 (*TP53*), menin (the *MEN1* gene involved in multiple endocrine neoplasia type 1), the *APC* gene involved in familial adenomatous polyposis coli, and the *PRKAR1A* gene encoding a cyclic adenosine monophosphate–dependent protein kinase regulatory subunit (also see Chapter 577).

Germline mutations in *TP53* (on chromosome 17p13.1) have been found in patients with isolated adrenal carcinoma as well as in patients with familial clustering of unusual malignancies; this latter condition is termed **Li-Fraumeni syndrome.** A 15-fold increased incidence of childhood adrenocortical tumors is found in southern Brazil, associated with a R337H mutation in *TP53*. Overexpression of insulin-like growth factor 2 (encoded by *IGF2*, on chromosome 11p15.5) occurs in 80% of sporadic childhood adrenocortical tumors, as well as in those associated with **Beckwith-Wiedemann syndrome,** in which there is loss of the normal imprinting of genes in this chromosomal region. Further implicating insulin-like growth factors (IGFs) in pathogenesis, many pediatric adrenocortical tumors overexpress the IGF receptor, IGF1R. Overexpression of steroidogenic factor-1 (SF1), a transcription factor required for adrenal development (see Chapter 574) is associated with decreased overall survival and recurrence-free survival when it occurs in adults with adrenocortical carcinomas, but it is seen in most pediatric adrenocortical tumors, where it does not seem to have prognostic significance. Conversely, the messenger RNA encoding the nephroblastoma overexpressed (NOV) protein (also termed cysteine-rich protein 61, or connective tissue growth factor, or nephroblastoma overexpressed gene-3) is significantly downregulated in childhood adrenocortical tumors. NOV is a selective proapoptotic factor for human adrenocortical cells, suggesting that abnormal apoptosis may play a role in childhood adrenocortical tumorigenesis.

Aldosterone-producing adenomas constitute a separate category from other adrenocortical tumors. They are very rarely malignant. The majority have mutations that activate the Wnt/β-catenin signaling pathway, either in β-catenin itself, or in the *APC* gene, which regulates this pathway. Additional, somatic mutations are often found in the potassium channel, KCNJ5, which probably first causes cell hypertrophy (see Chapter 576.8).

579.1 Virilizing and Feminizing Adrenal Tumors

Perrin C. White

CLINICAL MANIFESTATIONS

Virilization is the most common presenting symptom in children with adrenocortical tumors, occurring in 50-80%. In males, the clinical picture is similar to that of simple virilizing congenital adrenal hyperplasia: accelerated growth velocity and muscle development, acne, penile enlargement, and the precocious development of pubic and axillary hair. In females, virilizing tumors of the adrenal gland cause masculinization of a previously normal female with clitoral enlargement, growth acceleration, acne, deepening of the voice, and premature pubic and axillary hair development.

Conversely, adrenal tumors can occasionally (less than 10%) secrete high levels of estrogens as a result of overexpression of CYP19 (aromatase). Gynecomastia in males or premature thelarche in girls is often the initial manifestation. Growth and development may be otherwise normal, or concomitant virilization may occur.

In addition to virilization, 15-40% of children with adrenocortical tumors also have Cushing syndrome (see Chapter 577). Whereas isolated virilization occurs relatively frequently, children with adrenal tumors usually do not have Cushing syndrome alone.

In adults, adrenal tumors are frequently detected incident to CT or MRI imaging of the abdomen for other reasons; these are often referred to as **incidentalomas** (see Chapter 581.1). There are no published data on the frequency of the occurrence of such tumors in childhood. They are likely to be infrequent, being found in approximately 7% of autopsies of persons older than age 70 yr but in <1% of those younger than age 30 yr.

LABORATORY FINDINGS

Serum levels of dehydroepiandrosterone, dehydroepiandrosterone sulfate, and androstenedione are usually elevated, often markedly. Serum levels of testosterone are often increased, usually as a result of peripheral conversion of androstenedione, but infants with predominantly testosterone-secreting adenomas have been reported. Levels of estrone and estradiol are elevated in tumors from patients with feminizing signs. Urinary 17-ketosteroids (sex steroid metabolites) are also increased but are no longer routinely measured. Many adrenocortical tumors have a relative deficiency of 11β-hydroxylase activity and secrete increased amounts of deoxycorticosterone; these patients are hypertensive, and their tumors are often malignant.

Tumors can usually be detected by ultrasonography, CT, or MRI. Preoperatively, the presence of metastatic disease should be determined by MRI or CT of the chest, abdomen, and pelvis. Radiochemical imaging of these tumors by positron emission tomography with 11C-metomidate or single photon emission CT with ^{123}I-iodometomidate have been proposed but are not routinely available.

PATHOLOGIC FINDINGS

Differentiation between benign and malignant tumors by histologic criteria (architecture, cytologic atypia, mitotic activity, atypical mitotic figures) is usually not possible; almost all pediatric adrenocortical tumors would be classified as malignant by the criteria used to classify adult tumors. Size is a useful prognostic factor, with tumors weighing less than 200 g, 200-400 g, and >400 g being classified as low, intermediate, and high risk (>10 cm diameter has also been suggested as a high-risk category). Incomplete resection and gross local invasion or metastasis are also associated with a poor prognosis. However, most tumors occurring in children younger than 4 yr of age fall into favorable prognostic categories.

DIFFERENTIAL DIAGNOSIS

For functioning tumors, the differential diagnoses are those of the main presenting signs and symptoms. The differential diagnosis for Cushing syndrome is discussed in Chapter 577. For virilizing signs, the differential includes virilizing forms of adrenal hyperplasia (see Chapter 576) and factitious exposure to androgens, such as topical testosterone preparations. The differential diagnosis for hormonally inactive adrenocortical adenomas includes pheochromocytomas, adrenocortical carcinoma, and metastasis from an extraadrenal primary carcinoma (very rare in children). Careful history, physical examination, and endocrine evaluation must be performed to seek evidence of autonomous cortisol, androgen, mineralocorticoid, or catecholamine secretion. Not infrequently, a low level of autonomous cortisol secretion is detected that does not cause clinically apparent symptoms; this condition is sometimes referred to as "subclinical" Cushing syndrome.

TREATMENT

Functioning adrenocortical tumors should be removed surgically. There are no data on which to base a recommendation regarding nonfunctioning childhood incidentalomas; in adults, such tumors may be closely observed with imaging and repeat biochemical studies if smaller than 4 cm in diameter, but it is not certain that this is prudent in small children. Adrenalectomy may be performed either transperitoneally or laparoscopically. Some adrenocortical neoplasms are highly malignant and metastasize widely, but cure with regression of masculinizing or Cushingoid features may follow removal of less malignant, encapsulated tumors. Postoperatively, patients should be closely monitored biochemically, with frequent determinations of adrenal androgen levels and imaging studies. Recurrent symptoms or biochemical abnormalities should prompt a careful search for metastatic disease. Metastases primarily involve liver, lung, and regional lymph nodes. The majority of metastatic recurrences appear within 1 yr of tumor resection. Repeat surgical resection of metastatic lesions should be performed if possible and adjuvant therapy instituted. Radiation therapy has not been generally helpful. Antineoplastic agents such as cisplatin and etoposide, ifosfamide and carboplatin, and 5-fluorouracil and leucovorin have had limited use in children, and their success is not established. Therapy with o,p′-DDD (mitotane), an adrenolytic agent, may relieve the symptoms of hypercortisolism or virilization in recurrent disease. Treatment with higher doses of mitotane for more than 6 mo is associated with improved survival. Other agents that interfere with adrenal steroid synthesis, such as ketoconazole, aminoglutethimide, and metyrapone, may also relieve symptoms of steroid excess but do not improve survival.

A neoplasm of 1 adrenal gland may produce atrophy of the other because excessive production of cortisol by the tumor suppresses adrenocorticotropic hormone stimulation of the normal gland. Consequently, adrenal insufficiency may follow surgical removal of the tumor. This situation can be avoided by giving 10-25 mg of hydrocortisone every 6 hr, starting on the day of operation and weaned over 3-4 days postoperatively. Adequate quantities of water, sodium chloride, and glucose also must be provided.

Chapter 580
Pheochromocytoma
Perrin C. White

Pheochromocytomas are catecholamine-secreting tumors arising from chromaffin cells. The most common site of origin (approximately 90%) is the adrenal medulla; however, tumors may develop anywhere along the abdominal sympathetic chain and are likely to be located near the aorta at the level of the inferior mesenteric artery or at its bifurcation.

They also appear in the periadrenal area, urinary bladder or ureteral walls, thoracic cavity, and cervical region. Ten percent occur in children, in whom they present most frequently between 6 and 14 yr of age. Tumors vary from 1-10 cm in diameter; they are found more often on the right side than on the left. In more than 20% of affected children, the adrenal tumors are bilateral; in 30-40% of children, tumors are found in both adrenal and extraadrenal areas or only in an extraadrenal area.

ETIOLOGY

Pheochromocytomas may be associated with genetic syndromes such as **von Hippel-Lindau disease,** as a component of **multiple endocrine neoplasia** (MEN) syndromes MEN2A and MEN2B, and more rarely in association with **neurofibromatosis (type 1) or tuberous sclerosis.** The classic features of von Hippel-Landau syndrome, which occurs in 1 in 36,000 individuals, include retinal and central nervous system hemangioblastomas, renal clear cell carcinomas, and pheochromocytomas, but kindreds differ in their propensity to develop pheochromocytoma; in some kindreds, pheochromocytoma is the only tumor to develop. Germline mutations in the *VHL* tumor-suppressor gene on chromosome 3p25-26 have been identified in patients with this syndrome. Mutations of the *RET* protooncogene on chromosome 10q11.2 have been found in families with MEN2A and MEN2B. Patients with MEN2 are at risk of developing medullary thyroid carcinoma and parathyroid tumors; approximately 50% develop pheochromocytoma, with patients carrying mutations at codon 634 of the *RET* gene being at particularly high risk. Mutations are present in the *NF1* gene on chromosome 17q11.2 in neurofibromatosis type 1 patients.

Pheochromocytomas may occur in kindreds along with paragangliomas, particularly at sites in the head and neck. Such families typically carry mutations in the *SDHB*, *SDHD*, and, rarely, the *SDHC* genes encoding subunits of the mitochondrial enzyme succinate dehydrogenase.

Pheochromocytomas are also associated with tuberous sclerosis, Sturge-Weber syndrome, and ataxia-telangiectasia. Somatic mutations of the genes mentioned above, particularly *VHL,* have been found in some sporadic cases of pheochromocytoma (see Chapter 596).

CLINICAL MANIFESTATIONS

Pheochromocytomas detected by surveillance of patients who are known carriers of mutations in tumor-suppressor genes may be asymptomatic. Otherwise, patients are detected owing to hypertension, which results from excessive secretion of epinephrine and norepinephrine. All patients have hypertension at some time. Paroxysmal hypertension should particularly suggest pheochromocytoma as a diagnostic possibility, but in contrast to adults, the hypertension in children is more often sustained rather than paroxysmal. When there are paroxysms of hypertension, the attacks are usually infrequent at first, but become more frequent and eventually give way to a continuous hypertensive state. Between attacks of hypertension, the patient may be free of symptoms. During attacks, the patient complains of headache, palpitations, abdominal pain, and dizziness; pallor, vomiting, and sweating also occur. Convulsions and other manifestations of hypertensive encephalopathy may occur. In severe cases, precordial pains radiate into the arms; pulmonary edema and cardiac and hepatic enlargement may develop. Symptoms may be exacerbated by exercise, or with use of nonprescription medications containing stimulants such as pseudoephedrine. Patients have a good appetite but because of the hypermetabolic state may not gain weight, and severe cachexia may develop. Polyuria and polydipsia can be sufficiently severe to suggest diabetes insipidus. Growth failure may be striking. The blood pressure may range from 180-260 mm Hg systolic and from 120-210 mm Hg diastolic, and the heart may be enlarged. Ophthalmoscopic examination may reveal papilledema, hemorrhages, exudate, and arterial constriction.

LABORATORY FINDINGS

The urine may contain protein, a few casts, and occasionally glucose. Gross hematuria suggests that the tumor is in the bladder wall. Polycythemia is occasionally observed. The diagnosis is established by demonstration of elevated blood or urinary levels of catecholamines and their metabolites.

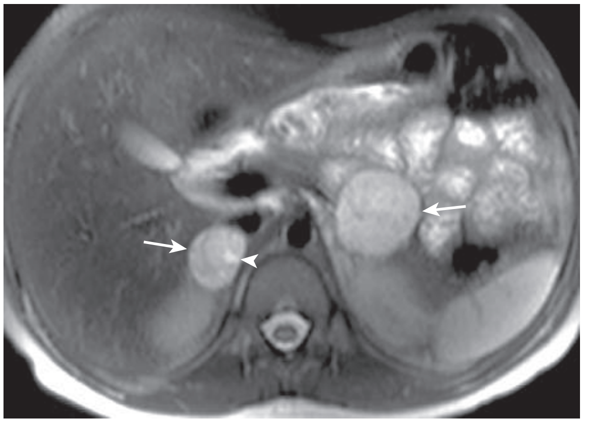

Figure 580-1 Bilateral pheochromocytoma in an 11 yr old boy with von Hippel-Lindau disease and arterial hypertension. An axial fat-suppressed T2-weighted magnetic resonance image shows bilateral adrenal masses *(arrows)*, larger on the left. The masses are hyperintense with small cystic change on the right medially. *(From Navarro OM, Daneman A. Acquired conditions. In Coley BD (ed):* Caffey's pediatric diagnostic imaging, *ed 12, Philadelphia, 2013, Elsevier, Fig. 123-9, p. 1283.)*

Pheochromocytomas produce norepinephrine and epinephrine. Normally, norepinephrine in plasma is derived from both the adrenal gland and adrenergic nerve endings, whereas epinephrine is derived primarily from the adrenal gland. In contrast to adults with pheochromocytoma in whom both norepinephrine and epinephrine are elevated, children with pheochromocytoma predominantly excrete norepinephrine in the urine. Total urinary catecholamine excretion usually exceeds 300 µg/24 hr. Urinary excretion of metanephrines (particularly normetanephrine) is also increased (see Fig. 574-3 in Chapter 574). Daily urinary excretion of these compounds by unaffected children increases with age. Although urinary excretion of vanillylmandelic acid (3-methoxy-4-hydroxymandelic acid), the major metabolite of epinephrine and norepinephrine, is increased, vanilla-containing foods and fruits can produce falsely elevated levels of this compound, which therefore is no longer routinely measured.

Elevated levels of free catecholamines and metanephrines can also be detected in plasma. In children, the best sensitivity and specificity are obtained by measuring plasma normetanephrine using gender-specific pediatric reference ranges, with plasma norepinephrine being next best. Plasma metanephrine and epinephrine are not reliably elevated in children. Additionally, the patient should be instructed to abstain from caffeinated drinks, and to avoid acetaminophen, which can interfere with plasma normetanephrine assays. If possible, the blood sample should be obtained from an indwelling intravenous catheter, to avoid acute stress associated with venipuncture.

Most tumors in the area of the adrenal gland are readily localized by CT or MRI (Fig. 580-1), but extraadrenal tumors may be difficult to detect. ^{123}I-metaiodobenzylguanidine is taken up by chromaffin tissue anywhere in the body and is useful for localizing small tumors. Venous catheterization with sampling of blood at different levels for catecholamine determinations is now only rarely necessary for localizing the tumor.

DIFFERENTIAL DIAGNOSIS

Various causes of hypertension in children must be considered, such as renal or renovascular disease; coarctation of the aorta; hyperthyroidism; Cushing syndrome; deficiencies of 11β-hydroxylase, 17α-hydroxylase, or 11β-hydroxysteroid dehydrogenase (type 2 isozyme); primary aldosteronism; adrenocortical tumors; and, rarely, essential hypertension (see Chapter 445). A nonfunctioning kidney may result

from compression of a ureter or of a renal artery by a pheochromocytoma. Paroxysmal hypertension may be associated with porphyria or familial dysautonomia. Cerebral disorders, diabetes insipidus, diabetes mellitus, and hyperthyroidism must also be considered in the differential diagnosis. Hypertension in patients with neurofibromatosis may be caused by renal vascular involvement or by concurrent pheochromocytoma.

Neuroblastoma, ganglioneuroblastoma, and ganglioneuroma frequently produce catecholamines, but urinary levels of most catecholamines are higher in patients with pheochromocytoma, although levels of dopamine and homovanillic acid are usually higher in neuroblastoma. Secreting neurogenic tumors often produce hypertension, excessive sweating, flushing, pallor, rash, polyuria, and polydipsia. Chronic diarrhea may be associated with these tumors, particularly with ganglioneuroma, and at times may be sufficiently persistent to suggest celiac disease.

TREATMENT

These tumors must be removed surgically, but careful preoperative, intraoperative, and postoperative management is essential. Preoperative **α- and β-adrenergic blockade** and **fluid loading** are required. Because these tumors are often multiple in children, a thorough transabdominal exploration of all the usual sites offers the best opportunity to find them all. Appropriate choice of anesthesia and expansion of blood volume with appropriate fluids during surgery are critical to avoid a precipitous drop in blood pressure during operation or within 48 hr postoperatively. Manipulation and excision of these tumors result in marked increases in catecholamine secretion that increase blood pressure and heart rate. Surveillance must continue postoperatively.

Although these tumors often appear malignant histologically, the only accurate indicators of malignancy are the presence of metastatic disease or local invasiveness that precludes complete resection, or both. Approximately 10% of all adrenal pheochromocytomas are malignant. Such tumors are rare in childhood; pediatric malignant pheochromocytomas occur more frequently in extraadrenal sites and are often associated with mutations in the *SDHB* gene encoding a subunit of succinate dehydrogenase. Prolonged follow-up is indicated because functioning tumors at other sites may be manifested many years after the initial operation. Examination of relatives of affected patients may reveal other individuals harboring unsuspected tumors that may be asymptomatic.

Chapter 581

Adrenal Masses

581.1 Adrenal Incidentaloma

Perrin C. White

Adrenal masses are discovered with increasing frequency in patients undergoing abdominal imaging for reasons unrelated to the adrenal gland. The rate of detection of single adrenal masses has ranged from less than 1% to more than 4% of abdominal CT examinations in adults. The unexpected discovery of such a mass presents the clinician with a dilemma in terms of diagnostic steps to undertake and treatment interventions to recommend. The differential diagnosis of adrenal incidentaloma includes benign lesions such as cysts, hemorrhagic cysts, hematomas, and myelolipomas. These lesions can usually be identified on CT or MRI. If the nature of the lesion is not readily apparent, additional evaluation is required. Included in the differential diagnosis of lesions requiring additional evaluation are benign adenomas, pheochromocytomas, adrenocortical carcinoma, and metastasis from an extraadrenal primary carcinoma. Benign, hormonally inactive adrenocortical adenomas make up the majority of incidentalomas. Careful history, physical examination, and endocrine evaluation must be performed to seek evidence of autonomous cortisol, androgen, mineralocorticoid, or catecholamine secretion. Functional tumors require removal. If the adrenal mass is nonfunctional and larger than 4-6 cm, recommendations are to proceed with surgical resection of the mass. Lesions of 3 cm or less should be followed clinically with periodic reimaging. Treatment must be individualized; nonsecreting adrenal incidentalomas may enlarge and become hyperfunctioning. Nuclear scan, and occasionally fine-needle aspiration, may be helpful in defining the mass.

581.2 Adrenal Calcification

Perrin C. White

Calcification within the adrenal glands may occur in a wide variety of situations, some serious and others of no obvious consequence. Adrenal calcifications are often detected as incidental findings in radiographic studies of the abdomen in infants and children. The physician may elicit a history of anoxia or trauma at birth. Hemorrhage into the adrenal gland at or immediately after birth is probably the most common factor that leads to subsequent calcification (see Fig. 575-1 in Chapter 575). Although it is advisable to assess the adrenocortical reserve of such patients, there is rarely any functional disorder.

Neuroblastomas, ganglioneuromas, cortical carcinomas, pheochromocytomas, and cysts of the adrenal gland may be responsible for calcifications, particularly if hemorrhage has occurred within the tumor. Calcification in such lesions is almost always unilateral.

In the past, tuberculosis was a common cause both of calcification within the adrenals and of Addison disease. Calcifications may also develop in the adrenal glands of children who recover from the Waterhouse-Friderichsen syndrome; such patients are usually asymptomatic. Infants with Wolman disease, a rare lipid disorder caused by a deficiency of lysosomal acid lipase, have extensive bilateral calcifications of the adrenal glands (see Chapter 86.4).

Section 5

Disorders of the Gonads

Chapter 582

Development and Function of the Gonads

Patricia A. Donohoue

GENETIC CONTROL OF EMBRYONIC GONADAL DIFFERENTIATION

Gonadal differentiation is a complex, multistep process that requires the sequential action and interaction of multiple gene products.

Early in the 1st trimester, the undifferentiated, bipotential fetal gonad begins as a thickening of the urogenital ridge, near the developing kidney and adrenal cortex. At 6 wk of gestation, the gonad contains germ cells, stromal cells that will become Leydig cells in testes, or theca, interstitial, or hilar cells in the ovary; and supporting cells that will develop into Sertoli cells in testes or granulosa cells in ovaries. In males, *SRY* (**s**ex-determining **r**egion on the **Y** chromosome) is transiently expressed, followed by a sequential upregulation of a number of testis-specific genes. SRY may also suppress a putative factor 2 that functions as repressor of male development. In the absence of SRY, the bipotential gonad will be able to develop into an ovary. Ovarian development is also characterized by expression of ovary-specific genes during the same time period. One such gene is *R-spondin1*. During the gestation time period of 6-9 wk, a number of genes are upregulated to the same degree in both the testis and the ovary, including *WNT4* and *CTNNB1*.

A chromosome complement of 46,XX is necessary for the development of **normal ovaries.** Both the long and short arms of the X chromosome contain genes for normal ovarian development. The DSS (**d**osage **s**ensitive/**s**ex reversal) locus associated with the *DAX1* (**D**SS **a**drenal hypoplasia on the **X** chromosome) gene, which is defective in patients with X-linked congenital adrenal hypoplasia and hypogonadotropic hypogonadism, is a member of the nuclear receptor superfamily and acts as a repressor of male gene expression. *DAX1* acts by binding to a related nuclear receptor SF-1 (**s**teroidogenic **f**actor-1). In vitro, the signaling gene *WNT4* stimulates expression of *DAX1,* resulting in the suppression of androgen synthesis in XX females. The WNTs are ligands that activate receptor-mediated signal transduction pathways and are involved in modulating gene expression as well as cell behavior, adhesion, and polarity. A key to its role in humans was elucidated by loss-of-function mutation of the *WNT4* gene that was found in an 18 yr old 46,XX woman. She had absence of müllerian-derived structures (uterus and fallopian tubes), unilateral renal agenesis, and clinical signs of androgen excess.

Mutations of the Wilms tumor 1 *(WT1)* gene, including alternative splicing, may also impact sex differentiation. *WT1* mutations are associated with the **Denys-Drash syndrome** (early-onset renal failure with abnormal external genitalia and Wilms tumor). Haploinsufficiency of a 3-amino-acid (KTS) form of *WT1* has been implicated in the gonadal dysgenesis of patients with **Fraser syndrome** (late-onset progressive glomerulopathy and 46,XY gonadal dysgenesis). Mutations in the *FOXL2* and *SF-1* genes are associated with ovarian failure. Mutation of the *R-spondin1* gene has been described in individuals with 46,XX DSD (**d**isorder of **s**ex **d**evelopment). Other autosomal genes also play a role in normal ovarian organogenesis and testicular development. Several conditions of gonadal dysgenesis are associated with gross abnormalities of both autosomes and sex chromosomes. A deletion affecting the short arm of the X chromosome produces the typical somatic anomalies of Turner syndrome.

Development of the testis requires the short arm of the Y chromosome; this contains the testis-determining factor *SRY* gene. During male meiosis, the Y chromosome must segregate from the X chromosome so that both X and Y chromosomes do not occur in the same spermatozoa. The major portion of the Y chromosome is composed of Y-specific sequences that do not pair with the X chromosome. However, a minor portion of the Y chromosome shares sequences with the X chromosome and pairing does occur in this region. The genes and sequences in this area recombine between the sex chromosomes, behaving like autosomal genes. Therefore, the term *pseudoautosomal region* is used to describe this portion of the chromosome, and the term indicates genetic behavior of these genes relative to pairing and recombinational events. The *SRY* gene is localized to the 35-kb portion proximal to the pseudoautosomal region of the Y chromosome. It contains a high-mobility group (HMG) nonhistone protein (HMG box), supporting SRY's role as a transcriptional regulator of other genes involved in sex differentiation. The gonadal ridge forms at around 33 days of gestation. SRY is detected at 41 days, peaks at 44 days when testis cords are first visible, and persists into adulthood.

Other genes that are found on autosomes are important in this process. *SOX9,* a *SRY*-related gene containing a region homologous with the HMG box 9 of *SRY,* is located on chromosome 17. Mutations of this gene result in XY sex reversal and camptomelic dysplasia. *SF-1* on chromosome 9q33 is important in adrenal and gonadal development, as well as the development of gonadotropin-releasing hormone–secreting neurons in the hypothalamus. *WTI,* especially the KST isoform on chromosome 11p13, is needed for early gonadal, adrenal, and renal development. Fibroblast growth factor-9, GATA-4, XH-2, and SOY9 are also important.

When genetic recombination events on sex chromosomes extend beyond the pseudoautosomal region, X- and Y-specific DNA may be transferred between the chromosomes. Such aberrant recombinations result in X chromosomes carrying *SRY*, resulting in **XX males**, or Y chromosomes that have lost *SRY*, resulting in **XY females.** SRY acts as a transcriptional regulator to increase cellular proliferation, attract interstitial cells from adjacent mesonephros into the genital ridge, and stimulate testicular Sertoli cell differentiation. Sertoli cells act as an organizer of steroidogenic and germ cell lines and produce **antimüllerian hormone** (AMH) that causes the female duct system to regress. Table 582-1 lists additional genes involved in sex development.

Development of the ovary was once thought to be a passive process in the absence of SRY. Although the morphologic changes in the developing ovary are less marked than in the testis, there are a number of sequentially expressed genes and pathways that are required for complete ovarian development as well as maintenance of ovarian integrity postnatally. One of these genes is *R-spondin1*, which if mutated can result in testicular or ovotesticular development in 46,XX individuals. Some peptides in the Wnt-signaling pathway may antagonize testicular development. This effect may be mediated by β-catenin signaling, which is required for suppressing testicular features. Once developed, the ovary requires FAX12 to preserve its differentiation and stability.

FUNCTION OF THE TESTES

Levels of placental chorionic gonadotropin peak at 8-12 wk of gestation and stimulate the fetal Leydig cells to secrete testosterone, the main hormonal product of the testis. In the classical androgen biosynthetic pathway, testosterone is then converted by the enzyme 5α-reductase to its more potent metabolite, dihydrotestosterone. This early period is critical for normal and complete virilization of the XY fetus. Defects in this process lead to different forms of atypical male development (see Chapter 588.2). After virilization occurs, fetal levels of testosterone decrease but are maintained at lower levels in the latter half of pregnancy by luteinizing hormone (LH) secreted by the fetal pituitary; this LH-mediated testosterone secretion is required for continued penile growth, and to some degree also for testicular descent.

As part of the normal transition from intrauterine to extrauterine life, perhaps related to the sudden withdrawal of maternal and placental hormones, newborns and young infants experience a transient surge of gonadotropins and sex steroids. This is the so-called minipuberty.

In males, LH and testosterone peak at 1-2 mo of age and then decline to reach prepubertal levels by 4-6 mo of age. Follicle-stimulating hormone (FSH), along with inhibin B, peak at 3 mo and decline to prepubertal levels by 9 and 15 mo, respectively. The LH rise is more dominant than that of FSH.

The neonatal surge may be important for postnatal maturation of the gonads, stabilization of male external genitalia, and perhaps also for gender identity and sexual behaviors. The postnatal surge in LH and testosterone is absent or blunted in infants with hypopituitarism, cryptorchidism, and complete androgen insensitivity syndrome. The development of nocturnal pulsatile secretion of LH marks the advent of puberty.

Within specific target cells, 6-8% of testosterone is converted by 5α-reductase to dihydrotestosterone, a more potent androgen (Fig. 582-1), and approximately 0.3% is acted on by aromatase to produce estradiol. Approximately half of circulating testosterone is bound to sex hormone–binding globulin and half to albumin; only 2% circulates in the free form. Plasma levels of sex hormone–binding globulin are low at birth, rise rapidly during the 1st 10 days of life, and then remain stable until the onset of puberty. Thyroid hormone may play a role in this

physiologic increase because neonates with athyreosis (absence of the thyroid gland) have very low levels of sex hormone–binding globulin.

AMH (antimüllerian hormone; previously referred to as *müllerian inhibitory substance*), **inhibin**, and **activin** are members of the transforming growth factor-β (TGF-β) superfamily of growth factors. This group, which has more than 45 members, also includes bone morphogenetic proteins. Members of the TGF-β superfamily are involved in the regulation of developmental processes and multiple diverse human disease states, including chondrodysplasias and cancer.

AMH, a homodimeric glycoprotein hormone encoded by a gene on chromosome 19, is the earliest secreted product of the Sertoli cells of the fetal testis. Produced as a prohormone, its carboxyterminal fragment is cleaved to make it active. *AMH* transcription is initiated by *SOX9* acting through the HMG box, while its expression is upregulated by SF-1 binding to its promoter and further interacting with *SOX9*, *WT1*, and *GATA4*. AMH binds to 2 distinct serine/threonine receptors, each having a single transmembrane domain. The activated type 1 receptor signals to the SMAD family of intracellular mediators.

The gene for the AMH receptor (on chromosome 12) is expressed in Sertoli cells. In the female, it is expressed in fetal müllerian duct cells and in fetal and postnatal granulosa cells. During sex differentiation in males, AMH causes involution of the müllerian ducts, which are embryologic precursors of the cervix and uterus. It works in concert with SF-1 to cause involution of the fallopian tubes.

AMH is secreted in males by Sertoli cells during both fetal and postnatal life. In females, it is secreted by granulosa cells from 36 wk of gestation to menopause but at lower levels. The serum concentration of AMH in males is highest at birth, whereas in females it is highest at puberty. After puberty, both sexes have similar serum concentrations of AMH. Its role in postnatal life is not yet fully characterized.

Inhibin is another glycoprotein hormone secreted by the Sertoli cells of the testes and granulosa and theca cells of the ovary. Inhibin A consists of an α-subunit disulfide linked to the β-A subunit, whereas inhibin B consists of the same α subunit linked to the β-B subunit. Activins are dimers of the B subunits, either homodimers (BA/BA, BB/BB) or heterodimers (BA/BB). Inhibins selectively inhibit whereas activins stimulate pituitary FSH secretion. By means of immunoassays specific for inhibin A or B, it has been shown that inhibin A is absent in males and is present mostly in the luteal phase in women. Inhibin B is the principal form of inhibin in males and in females during the follicular phase. Inhibin B may be used as a marker of Sertoli cell function in males. FSH stimulates inhibin B secretion in females and males, but only in males is there also evidence for gonadotropin-independent regulation. Levels of inhibin B are currently being studied in children with various forms of gonadal and pubertal disorders. In males with delayed puberty, inhibin B may be a useful screening test to differentiate between constitutional delay of puberty and hypogonadotropic hypogonadism. In hypogonadotropic hypogonadism, the serum inhibin B level is very low to undetectable.

Like inhibin and activin, follistatin (a single-chain glycosylated protein) is produced by gonads and other tissues such as the hypothalamus, kidney, adrenal gland, and placenta. Follistatin inhibits FSH secretion principally by binding activins, thereby blocking the effects of activins at the level of both ovary and pituitary.

Many additional peptides act as mediators of the development and function of the testis. They include neurohormones such as growth hormone–releasing hormone, gonadotropin-releasing hormone, corticotropin-releasing hormone, oxytocin, arginine vasopressin, somatostatin, substance P, and neuropeptide Y; growth factors such as insulin-like growth factors and insulin-like growth factor–binding proteins, TGF-β, and fibroblast, platelet-derived, and nerve growth factors; vasoactive peptides; and immune-derived cytokines such as tumor necrosis factor and interleukins 1, 2, 4, and 6.

Clinical patterns of pubertal changes vary widely (see Chapters 14 and 561 covering pubertal maturation). In 95% of boys, enlargement of the genitals begins between 9.5 and 13.5 yr of age, reaching maturity at 13-17 yr of age. In a minority of normal boys, puberty begins after 15 yr of age. In some boys, pubertal development is completed in less than 2 yr, but in others it may take longer than 4.5 yr. Pubertal development and the adolescent growth spurt occur at an older age in boys than in girls.

The median age of sperm production (spermarche) is 14 yr. This event occurs in midpuberty as judged by pubic hair, testis size, evidence of growth spurt, and testosterone levels. Nighttime levels of FSH are in the adult male range at the time of spermarche; the first conscious ejaculation occurs at about the same time.

FUNCTION OF THE OVARIES

In the normal female, the undifferentiated gonad can be identified histologically as an ovary by 10-11 wk of gestation, after the upregulation of *R-spondin1*. Oocytes are present from the 4th mo of gestation and reach a peak of 7 million by 5 mo of gestation. For normal maintenance, oocytes need granulosa cells to form primordial follicles. Functional FSH (but not LH) receptors are present in oocytes of primary follicles during follicular development. Normal X chromosomes are needed for maintenance of oocytes. In contrast to somatic cells, in which only 1 X chromosome is active, both Xs are active in germ cells. At birth, the ovaries contain approximately 1 million active follicles, which decrease to 0.5 million by menarche. Thereafter, they decrease at a rate of 1,000/mo, and at an even higher rate after the age of 35 yr.

The hormones of the fetal ovary are provided in most part by the fetoplacental unit. As in males, peak gonadotropin secretion occurs in fetal life and then again at 2-3 mo of life, with the lowest levels at about 6 yr of age. By contrast to males, the FSH surge predominates over LH in females. FSH peaks around 3-6 mo of age, declines by 12 mo, but remains detectable for 24 mo. Under LH influence, estradiol peaks at 2-6 mo of age. The inhibin B response is variable, peaking between 2 and 12 mo and remaining above prepubertal levels until 24 mo. In both infancy and childhood, gonadotropin levels are higher in females than in males.

The most important estrogens produced by the ovary are estradiol-17β (E_2) and estrone (E_1); estriol is a metabolic product of these 2, and all 3 estrogens may be found in the urine of mature females. Estrogens also arise from androgens produced by the adrenal gland and both the female and male gonads (see Fig. 574-1 in Chapter 574). This conversion explains why in certain types of disorders of sex differentiation in males, feminization occurs at puberty. In 17-ketosteroid reductase deficiency, for example, the enzymatic block results in markedly increased secretion of androstenedione, which is converted in the peripheral tissues to estradiol and estrone. These estrogens, in addition to those directly secreted by the testis, result in gynecomastia. Estradiol produced from testosterone in the complete androgen insensitivity syndrome causes complete feminization in XY individuals.

Estrogen regulates a host of functionally different activities in multiple tissues. There are at least 2 distinct estrogen receptors with different expression patterns. The ovary also synthesizes progesterone, the main progestational steroid; the adrenal cortex and testis also synthesize progesterone where it is a precursor for other adrenal and testicular hormones.

A host of other hormones with autocrine, paracrine, and intracrine effects have been identified in the ovary. They include inhibins, activins, relaxin, and growth factors insulin-like growth factor-1, TGF-α and TGF-β, and cytokines.

Plasma levels of estradiol increase slowly but steadily with advancing sexual maturation and correlate well with clinical evaluation of pubertal development, skeletal age, and rising levels of FSH. Levels of LH do not rise until secondary sexual characteristics are well developed. Estrogens, like androgens, inhibit secretion of both LH and FSH (negative feedback). In females, estrogens also provoke the surge of LH secretion that occurs in the mid–menstrual cycle. The capacity for this positive feedback is another maturational milestone of puberty.

The average age at menarche in American girls is approximately 12.5-13 yr, but the range of "normal" is wide, and 1-2% of normal girls have not menstruated by 16 yr of age. The age at onset of pubertal signs varies, with recent studies suggesting earlier ages than previously thought, especially in the U.S. African-American population (see Chapter 561). Menarche generally correlates closely with skeletal age. Maturation and closure of the epiphyses is at least partially estrogen dependent, as demonstrated by a very tall 28 yr old, normally masculinized male with continued growth as a result of incomplete closure of the epiphyses, who proved to have complete estrogen insensitivity caused by an estrogen-receptor defect.

DIAGNOSTIC TESTING

Improved, sensitive, and specific assays for pituitary and gonadal hormones that can be measured in small amounts of blood have contributed to rapid advances in the understanding of normal and abnormal hypothalamic-pituitary-gonadal interactions. In male infants, measurements of LH, FSH, and testosterone can detect pituitary and testicular defects. Leydig cell integrity in childhood can be determined by the testosterone response following human chorionic gonadotropin administration. (One protocol is to use 5,000 IU IM daily for 3 days; other protocols are available.) The integrity, as well as the maturity, of the hypothalamic-pituitary-gonadal axis in males and females can be assessed by measuring serial sex steroid, LH, and FSH levels after the subcutaneous administration of the gonadotropin-releasing hormone analog leuprolide. An ultrasensitive LH assay has been shown to

differentiate between boys with delayed puberty and those with complete, but not partial, hypogonadotropic hypogonadism.

The normal range for inhibin B levels has been established in infant boys. Inhibin B may be a marker of spermatogenesis and also of tumors such as granulosa cell tumors. Inhibin may be involved in tumor suppression. Estrogen-receptor assays may be clinically useful in the management of various ovarian cancers. AMH measurements are useful in the evaluation of children with nonpalpable gonads and disorders of sex development.

THERAPEUTIC USE OF SEX STEROIDS

The estrogenic effects of polyhalogenated aromatic hydrocarbons may in part be a result of inhibition of estradiol sulfation by estrogen sulfotransferase, an important pathway of estradiol inactivation. Naturally occurring estrogens administered orally are rapidly destroyed by gastrointestinal and liver enzymes; accordingly, they are usually given as conjugates or esters. The most widely used oral preparations are equine conjugated estrogens (Premarin) and ethinyl estradiol. Estrogen-containing skin patches for transdermal absorption are also used. With improvements in the understanding of estrogen and estrogen-receptor interactions, a new class of compounds called *selective estrogen-receptor modulators* has been synthesized. For example, raloxifene, a nonsteroidal benzothiophene derivative, acts as an estrogen agonist in bone and liver and as an estrogen antagonist in breast and uterus.

Androgens, such as testosterone, are generally injected intramuscularly as long-acting esters (enanthate or cypionate, most commonly) because of their potency and steady response. Transdermal testosterone patches and a cutaneously applied gel have to date been used mostly in adults with hypogonadism because of the difficulty in titrating the doses needed during childhood and adolescence. Oral preparations, such as methyltestosterone or fluoxymesterone, do not produce so potent an androgenic response and may be hepatotoxic. Testosterone undecenoate, another oral preparation, is used in Europe but not in the United States. Sublingual (microspheres or pellets) and buccal (absorption via the buccal mucosa) preparations of testosterone are in development.

Chapter 583
Hypofunction of the Testes

Omar Ali and Patricia A. Donohoue

Testicular hypofunction during fetal life can be a component of some types of **disorders of sex development** (see Chapter 588.2) and may lead to varying degrees of ambiguous genitalia. After birth, neonates undergo "minipuberty" with relatively high levels of gonadotropins and sex steroids, but this phenomenon is transient and its absence does not lead to any obvious clinical findings. Because prepubertal children normally do not produce significant amounts of testosterone and are not yet producing sperm, there are no discernible effects of testicular hypofunction in this age group. Testicular hypofunction from the age of puberty onward may lead to testosterone deficiency, infertility, or both. Such hypofunction may be primary in the testes **(primary hypogonadism)** or secondary to deficiency of pituitary gonadotropic hormones **(secondary hypogonadism).** Both types may be caused by inherited genetic defects or acquired causes, and in some cases the etiology may be unclear, but the level of the lesion (primary or secondary) is usually well defined; patients with primary hypogonadism have elevated levels of gonadotropins (hypergonadotropic); those with secondary hypogonadism have inappropriately low or absent levels

Table 583-1	Etiologic Classification of Male Hypogonadism

583.1 Hypergonadotropic Hypogonadism in the Male (Primary Hypogonadism)

Omar Ali and Patricia A. Donohoue

ETIOLOGY

Some degree of testicular function is essential in the development of phenotypically male newborns. If testicular function is present, sex differentiation is normally complete by the 14th wk of intrauterine life. Hypogonadism may occur after phenotypically male genitalia have developed for a variety of reasons; genetic or chromosomal anomalies may lead to testicular hypofunction that does not become apparent until the time of puberty, when these boys may have delayed or incomplete pubertal development. In other cases, normally developed testes may be damaged by infarction, trauma, radiation, chemotherapy, infections, infiltration, or other causes after sexual differentiation has occurred. In some cases, genetic defects may predispose to atrophy or maldescent; or torsion or infarction or may lead to progressive testicular damage and atrophy after a period of normal development. If testicular compromise is global, both testosterone secretion and fertility

(sperm production) are likely to be affected. Even when the primary defect is in testosterone production, low levels of intratesticular testosterone will frequently lead to infertility. The reverse is not necessarily true. Defects in sperm production and in the storage and transit of sperm may not be associated with low testosterone levels; infertility may thus be seen in patients with normal testosterone levels, normal libido, and normal secondary sexual characteristics.

Various degrees of primary hypogonadism also occur in a significant percentage of patients with chromosomal aberrations as in **Klinefelter syndrome, males with more than one X chromosome**, and **XX males.** These chromosomal anomalies are associated with other characteristic findings. Noonan syndrome is associated with cryptorchidism and infertility, but other (nongonadal) features dominate its clinical picture.

Congenital Anorchia or Testicular Regression Syndrome

Boys in whom the external genitalia have developed normally (or nearly normally) and müllerian duct derivatives (uterus, fallopian tubes) are absent have obviously had testicular function for at least some part of gestation. If their testes cannot be palpated at birth, they are said to have **cryptorchidism.** In most such cases, the testes are undescended or retractile, but in some cases no testes are found in any location, even after extensive investigation. This syndrome of absence of testes in a phenotypic male with normal 46,XY karyotype (indicating that there was some period of testicular function in intrauterine life) is known as "vanishing testes," "congenital anorchia," or **"testicular regression syndrome."**

Testicular regression syndrome is not uncommon. Cryptorchidism occurs in 1.5-9% of male births and in 10-20% of these cases, the testes are impalpable. Of children with impalpable testes, up to 50% may have no detectable testes after extensive investigation. Most cases appear to be sporadic and are thought to be a result of torsion or vascular accidents. The incompletely descended testis may be more prone to torsion and this may be one of the causes of "vanishing testes." Most cases are sporadic but in a subset of patients testicular regression syndrome occurs in monozygotic twins or in families with other affected individuals, suggesting a genetic etiology. Some cases are associated with micropenis and in these cases the testicular loss probably occurred after the 14th wk, but well before the time of birth, or this may indicate a preexisting dysfunction of male hormonal development. Low levels of testosterone (<10 ng/dL) and markedly elevated levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are found in the early postnatal months; thereafter, levels of gonadotropins tend to decrease even in agonadal children, rising to very high levels again as the pubertal years approach. Stimulation with human chorionic gonadotropin (hCG) fails to evoke an increase in the level of testosterone. Serum levels of antimüllerian hormone (AMH) are undetectable or low. All patients with undetectable testes should be tested for AMH and should undergo an hCG stimulation test. If the results indicate that no testicular tissue is present (absent AMH and no rise in testosterone after hCG stimulation), then the diagnosis of testicular regression syndrome is confirmed. If testosterone secretion is demonstrated, then imaging with abdominal MRI and/or surgical exploration is indicated. A small fibrotic nodule may be found at the end of the spermatic cord in many cases of testicular regression syndrome. Treatment of male hypogonadism (primary or secondary) is discussed in Chapter 583.2. There is no possibility of normal fertility in these patients.

Chemotherapy and Radiation-Induced Hypogonadism

Testicular damage is a frequent consequence of **chemotherapy** and **radiotherapy** for cancer. The frequency and extent of damage depend on the agent used, total dose, duration of therapy, and posttherapy interval of observation. Another important variable is age at therapy; germ cells are less vulnerable in prepubertal than in pubertal and postpubertal boys. **Chemotherapy** is most damaging if more than 1 agent is used. The use of alkylating agents such as cyclophosphamide in prepubertal children does not impair pubertal development, even though there may be biopsy evidence of germ cell damage. High doses of cyclophosphamide and ifosfamide are associated with infertility. Cisplatin causes transient azoospermia or oligospermia at lower doses, while higher doses (400-600 mg/m^2) can cause permanent infertility. Interleukin 2 can depress Leydig cell function, whereas interferon-α does not seem to affect gonadal function. Most chemotherapeutic agents produce azoospermia and infertility; Leydig cell damage (leading to low testosterone levels) is less common. In many cases, the damage is transient and sperm counts recover after 12-24 mo. Both chemotherapy and radiotherapy are associated with an increase in the percentage of abnormal gametes, but data concerning the outcomes of pregnancies after such therapy have *not* shown any increase in genetically mediated birth defects, possibly because of selection bias against abnormal sperm.

Radiation damage is dose dependent. Temporary oligospermia can be seen with doses as low as 0.1 Gy, with permanent azoospermia seen with doses greater than 2 Gy. Recovery of spermatogenesis can be seen as long as 5 yr (or more) after irradiation, with higher doses leading to slower recovery. Leydig cells are more resistant to irradiation. Mild damage as determined by elevated LH levels can be seen with up to 6 Gy; doses greater than 30 Gy cause hypogonadism in most patients. Whenever possible, testes should be shielded from irradiation. Testicular function should be carefully evaluated in adolescents after multimodal treatment for cancer in childhood. Replacement therapy with testosterone and counseling concerning fertility may be indicated. The storage of sperm prior to chemotherapy or radiation treatment in postpubertal males is an option. Even in those cases where sperm counts are abnormal, recovery is possible, though the chances of recovery decline with increasing dose of radiation. If sperm counts remain low, fertility is still possible in some cases with testicular sperm extraction and intracytoplasmic sperm injection.

Sertoli Cell–Only Syndrome

Small testes and azoospermia are seen in patients with the extremely rare Sertoli cell–only syndrome (germ cell aplasia, or **Del Castillo syndrome**). These patients have no germ cells in the testes, but usually have normal testosterone production, and present as adults with the complaint of infertility. Most cases are sporadic and idiopathic, but deletions involving the azoospermia factor (AZF) region of the Y chromosome (Yq11) may be found in some cases.

Other Causes of Testicular Hypofunction

Atrophy of the testes may follow damage to the vascular supply as a result of manipulation of the testes during surgical procedures for correction of cryptorchidism or as a result of bilateral torsion of the testes. **Acute orchitis** is common in pubertal or adult males with mumps and may lead to subfertility in 13% of cases, though infertility is rare. Testosterone secretion usually remains normal. The incidence of mumps orchitis in postpubertal males has increased in some areas as a result of decrease in measles, mumps, and rubella vaccination uptake. Autoimmune polyendocrinopathy may be associated with primary hypogonadism (associated with anti-P450scc antibodies) but this appears to be more common in females.

Testicular Dysgenesis Syndrome

The incidence of testicular cancer has increased in many developed societies while the incidence of cryptorchidism, hypospadias, low sperm counts, and sperm abnormalities also appears to have increased in some, but not all, studies. It has been proposed that all these trends are linked by prenatal testicular dysgenesis. The hypothesis is that some degree of testicular dysgenesis develops in intrauterine life from genetic as well as environmental factors, and is associated with increased risk of cryptorchidism, hypospadias, hypofertility, and testicular cancer. The environmental influences that have been implicated in this syndrome include environmental chemicals that act as endocrine disruptors, such as bisphenol A and phthalates (components of many types of plastics), several pesticides, phytoestrogens or mycoestrogens, and other chemicals. The fact that these lesions can be reproduced in some animal models by environmental chemicals has led to efforts to remove

these chemicals from products used by infants and pregnant mothers, and from the environment in general. Nonetheless, the evidence is only suggestive and is not conclusive.

CLINICAL MANIFESTATIONS

Primary hypogonadism may be suspected at birth if the testes and penis are abnormally small. Normative data are available for different populations. The condition often is not noticed until puberty, when secondary sex characteristics fail to develop. Facial, pubic, and axillary hair is scant or absent; there is neither acne nor regression of scalp hair; and the voice remains high pitched. The penis and scrotum remain infantile and may be almost obscured by pubic fat; the testes are small or not palpable. Fat accumulates in the region of the hips and buttocks and sometimes in the breasts and on the abdomen. The epiphyses close later than normal; therefore, extremities are long. The span may be several inches longer than the height, and the distance from the symphysis pubis to the soles of the feet (lower segment) is much greater than that from the symphysis to the vertex (upper segment). The proportions of the body are described as **eunuchoid.** The upper to lower segment ratio is considerably less than 0.9. Many individuals with milder degrees of hypogonadism may be detected only by appropriate studies of the pituitary-gonadal axis. Examination of the testes should be performed routinely by pediatricians; testicular volumes as determined by comparison with standard orchidometers or by measurement of linear dimensions should be recorded.

DIAGNOSIS

Levels of serum FSH and, to a lesser extent, of LH are elevated to greater than age-specific normal values in early infancy (when "minipuberty" normally occurs and the gonadotropins are normally disinhibited). This is followed by a period of time when even agonadal children may not exhibit significant elevation in gonadotropins, indicating that the gonadotropins are also suppressed at this stage by some mechanism independent of feedback inhibition by gonadal hormones. In the latter half of childhood and several years prior to the onset of puberty, this inhibition is released and gonadotropin levels again rise above age-matched normals in subjects with primary hypogonadism. These elevated levels indicate that even in the prepubertal child there is an active hypothalamic-gonadal feedback relationship. After the age of 11 yr, FSH and LH levels rise significantly, reaching the castrate range. Measurements of random plasma testosterone levels in prepubertal boys are not helpful because they are ordinarily low in normal prepubertal children, rising during puberty to attain adult levels. During puberty, these levels, when measured in an early-morning blood sample, correlate better with testicular size, stage of sexual maturity, and bone age than with chronological age. In patients with primary hypogonadism, testosterone levels remain low at all ages. There is an attenuated rise or no rise at all after administration of hCG, in contrast to normal males in whom hCG produces a significant rise in plasma testosterone at any stage of development.

AMH is secreted by the Sertoli cells and this secretion is suppressed by testosterone. As a result, AMH levels are elevated in prepubertal boys and suppressed at onset of puberty. Boys with primary hypogonadism continue to have elevated AMH levels in puberty. Detection of AMH may be used in prepubertal years as an indicator of the presence of testicular tissue (e.g., in patients with bilateral cryptorchidism). Inhibin B is also secreted by the Sertoli cells, is present throughout childhood, and rises at onset of puberty (more in boys than in girls). It may be used as another marker of the presence of testicular tissue in bilateral cryptorchidism and as a marker of spermatogenesis (e.g., in delayed puberty, cancer survivors, and patients with Noonan syndrome). Bone age x-rays are useful to document delayed bone age in patients with constitutional growth delay as well as primary hypogonadism.

NOONAN SYNDROME

Etiology

The term *Noonan syndrome* has been applied to males and females with normal karyotypes who have certain phenotypic features that occur also in females with Turner syndrome (although the genetic causes are completely distinct) (see Chapter 81.4). Noonan syndrome occurs in 1 in 1,000-2,500 live births. Approximately 20% of the cases are familial and exhibit autosomal dominant inheritance. Males and females are equally affected. It is now thought that several mutations in the renin–angiotensin system (RAS)–mitogen-activated protein kinase (MAPK) pathway can cause Noonan syndrome and other related disorders and such mutations are currently detected in approximately 70% of the cases of Noonan syndrome. Missense mutations in *PTPN11*—a gene on chromosome 12q24.1 encoding the nonreceptor protein tyrosine phosphatase SHP-2—are seen in about half the cases. Mutations in other genes in this pathway, including *SHOC2*, *CBL*, *SOS1*, *KRAS*, *NRAS*, *BRAF*, and *RAF1*, as well as duplications of the 12q24 region, are also seen. Phenotypic features of Noonan syndrome therefore overlap with other syndromes involving the RAS-MAPK pathway, such as Leopard syndrome and cardiofaciocutaneous syndrome.

Clinical Manifestations

The most common abnormalities are short stature, webbing of the neck, pectus carinatum or pectus excavatum, cubitus valgus, right-sided congenital heart disease, and characteristic facies. Hypertelorism, epicanthus, downward-slanting palpebral fissures, ptosis, micrognathia, and ear abnormalities are common. Other abnormalities such as clinodactyly, hernias, and vertebral anomalies occur less frequently. As opposed to Turner syndrome, the mean IQ of school-age children with Noonan syndrome is subnormal at 86, with a range of 53-127. Verbal IQ tends to be better than performance IQ. High-frequency sensorineural hearing loss is common. The cardiac defect is most often pulmonary valvular stenosis, hypertrophic cardiomyopathy, or atrial septal defect. Hepatosplenomegaly and several hematologic diseases, including low clotting factors XI and XII, acute lymphoblastic leukemia, and chronic myelomonocytic leukemia, are noted. Noonan-like features can be part of the phenotypic variation of the *NF1* (neurofibromatosis) gene mutation, possibly as a result of common involvement of the RAS-MAPK pathway in both diseases. Males frequently have cryptorchidism and small testes. Testosterone secretion may be low or normal, but spermatogenesis may be affected even in those with normal testosterone (and normal secondary sexual characteristics). Serum inhibin-B is a useful marker of Sertoli cell function in these patients. Puberty is delayed and adult height is achieved by the end of the 2nd decade and usually reaches the lower limit of the normal population. Prenatal diagnosis should be suspected in fetuses with normal karyotype, edema, or hydrops and short femur length.

Treatment

Human growth hormone results in improvement in growth velocity in many Noonan syndrome patients, comparable to that seen in patients with Turner syndrome, and studies show a mean increase in height standard deviation score ranging from 1.3-1.7, corresponding to 9.5-13 cm for boys and 9.0-9.8 cm for girls. Many patients with Noonan syndrome reach normal height without growth hormone therapy, but treatment is recommended for those who fall below the 3rd percentile for height. The recommended dose is up to 66 µg/kg/day of recombinant growth hormone. Patients with Noonan syndrome and demonstrable *PTNP11* mutations grow less well and are less responsive to growth hormone treatment than those without mutations. They have lower insulin-like growth factor-1 and higher growth hormone levels, suggesting partial growth hormone resistance because of post–receptor-signaling defects. Treatment of male hypogonadism is discussed in Chapter 583.2.

KLINEFELTER SYNDROME

See also Chapter 81.

Etiology

Klinefelter syndrome is the most common sex chromosomal aneuploidy in males, with an incidence of 0.1-0.2% in the general population (1 in 500-1,000) and rising to 4% among infertile males and 10-11% in those with oligospermia or azoospermia. Approximately 80% of them have a 47,XXY chromosome complement, while mosaics

and higher degrees of polyX are seen in the remaining 20%. Even with as many as 4 X chromosomes, the Y chromosome determines a male phenotype. The chromosomal aberration most often results from meiotic nondisjunction of an X chromosome during parental gametogenesis; the extra X chromosome is maternal in origin in 54% and paternal in origin in 46% of patients. A national study in Denmark revealed a prenatal prevalence of 213 per 100,000 male fetuses, but in adult men the prevalence was only 40 per 100,000, suggesting that only 1 in 4 of adult males with Klinefelter syndrome was diagnosed.

Clinical Manifestations

In patients who do not have a prenatal diagnosis, the diagnosis is rarely made before puberty because of the paucity or subtleness of clinical manifestations in childhood. Behavioral or psychiatric disorders may be apparent long before defects in sexual development. These children tend to have learning disabilities and deficits in "executive function" (concept formation, problem solving, task switching, and planning), and the condition should be considered in boys with psychosocial, learning, or school adjustment problems. Affected children may be anxious, immature, or excessively shy and tend to have difficulty in social interactions throughout life. In a prospective study, a group of children with 47,XXY karyotypes identified at birth exhibited relatively mild deviations from normal during the 1st 5 yr of life. None had major physical, intellectual, or emotional disabilities; some were inactive, with poorly organized motor function and mild delay in language acquisition. Problems often first become apparent after the child begins school. Full-scale IQ scores may be normal, with verbal IQ being somewhat decreased. Verbal cognitive defects and underachievement in reading, spelling, and mathematics are common. By late adolescence, many boys with Klinefelter syndrome have generalized learning disabilities, most of which are language based. Despite these difficulties, most complete high school.

The patients tend to be tall, slim, and have a specific tendency to have long legs (disproportionate to the arms, and longer than those seen with other causes of hypogonadism), but body habitus can vary markedly. The testes tend to be small for age, but this sign may become apparent only after puberty, when normal testicular growth fails to occur. The phallus tends to be smaller than average, and cryptorchidism is more common than in the general population. Bone mineral density may be low in adults with Klinefelter syndrome and this correlates with lower testosterone levels.

Pubertal development may be delayed, although some children undergo apparently normal or nearly normal virilization. Despite normal testosterone levels, serum LH and FSH concentrations and their responses to gonadotropin-releasing hormone (GnRH) stimulation are elevated starting at around 13 yr of age. Approximately 80% of adults have **gynecomastia;** they have sparser facial hair, most shaving less often than daily. The most common testicular lesions are spermatogenic arrest and Sertoli cell predominance. The sperm have a high incidence of sex chromosomal aneuploidy. Azoospermia and infertility are usual, although rare instances of fertility are known. It is now clear that germ cell numbers and sperm counts are higher in early puberty and decline with age. Testicular sperm extraction followed by intracytoplasmic sperm injection can result in the birth of healthy infants, with success rates declining with increasing age. In nonmosaic Klinefelter patients, most testicular sperm (94%) have a normal pattern of sex chromosome segregation, indicating that meiotic checkpoints can remove most aneuploid cells. Antisperm antibodies have been detected in 25% of tested specimens.

There is an increased incidence in adulthood of central adiposity, metabolic syndrome, pulmonary disease, varicose veins, and cancer of the breast. Among 93 unselected **male breast cancer** patients, 7.5% were found to have Klinefelter syndrome. Mediastinal germ cell tumors have been reported; some of these tumors produce hCG and cause precocious puberty in young boys. They may also be associated with leukemia, lymphoma, and other hematologic neoplasia. The highest cancer risk (relative risk: 2.7) occurs in the 15-30 yr age group. A large cohort study in Britain demonstrated an overall significantly increased standardized mortality ratio (1.5), with particular increases in deaths from diabetes, epilepsy, peripheral and intestinal vascular sufficiency, pulmonary embolism, and renal disease. Mortality from ischemic heart disease was decreased. In adults, structural brain abnormalities correlate with cognitive deficits.

In adults with XY/XXY mosaicism, the features of Klinefelter syndrome are decreased in severity and frequency. Children with mosaicism have a better prognosis for virilization, fertility, and psychosocial adjustment.

Klinefelter Variants and Other Poly-X Syndromes

When the number of X chromosomes exceeds 2, the clinical manifestations, including mental retardation and impairment of virilization, are more severe. Height decreases with increasing number of X chromosomes. The XXYY variant is the most common variant (1 in 18,000-40,000 male births). In most, mental retardation occurs with IQ scores between 60 and 80, but 10% have IQs greater than 110. The XXYY male phenotype is not distinctively different from that of the XXY patient, except that XXYY adults tend to be taller than the average XXY patient. The 49,XXXXY variant is sufficiently distinctive to be detected in childhood. Its incidence is estimated to be 1 in 80,000-100,000 male births. The disorder arises from sequential nondisjunction in meiosis. Affected patients are severely cognitively impaired and have short necks and typical coarse facies with wide-set eyes with a mild upward slant of the fissures, epicanthus, strabismus, a wide and flat upturned nose, a large open mouth, and large malformed ears. The testes are small and may be undescended, the scrotum is hypoplastic, and the penis is very small. Defects suggestive of Down syndrome (short, incurved terminal 5th phalanges, single palmar creases, and hypotonia) and other skeletal abnormalities (including defects in the carrying angle of the elbows and restricted supination) are common. The most frequent radiographic abnormalities are radioulnar synostosis or dislocation, elongated radius, pseudoepiphyses, scoliosis or kyphosis, coxa valga, and retarded osseous age. Most patients with such extensive changes have a 49,XXXXY chromosome karyotype; several mosaic patterns have also been observed: 48,XXXY/49,XXXXY; 48,XXXY/49,XXXXY/50,XXXXXY; and 48,XXXY/49,XXXXY/50,XXXXYY. Prenatal diagnosis of a 49,XXXXY infant has been reported. The fetus had intrauterine growth retardation, edema, and cystic hygroma colli.

The 48,XXXY variant is relatively rare. The characteristic features are generally less severe than those of patients with 49,XXXXY and more severe than those of 47,XXY patients. Mild intellectual disability, delayed speech and motor development, and immature but passive and pleasant behavior are associated with this condition.

Very few patients have been described with 49,XYYY and 49,XXYYY karyotypes. Dysmorphic features and cognitive impairment are common to both.

Laboratory Findings

Most males with Klinefelter syndrome go through life undiagnosed. The chromosomes should be examined in all patients suspected of having Klinefelter syndrome, particularly those attending child guidance, psychiatric, and cognitive disability clinics. In infancy, inhibin B and AMH levels are normal but testosterone levels are lower than in controls. Before 10 yr of age, boys with 47,XXY Klinefelter syndrome have normal basal plasma levels of FSH and LH. Responses to gonadotropin-stimulating hormone and to hCG are normal. The testes show normal growth early in puberty, but by midpuberty the testicular growth stops, gonadotropins become elevated, and testosterone levels are slightly low. Inhibin B levels are normal in early puberty, decrease in late puberty, and are low in adults with the syndrome. Elevated levels of estradiol, resulting in a high estradiol to testosterone ratio, account for the development of gynecomastia during puberty. Sex hormone–binding globulin levels are elevated, further decreasing free testosterone levels. Long androgen receptor polyglutamine (CAG) repeat length is associated with the more-severe phenotype, including gynecomastia, small testes, and short penile length.

Testicular biopsy before puberty may reveal only deficiency or absence of germinal cells. After puberty, the seminiferous tubular membranes are hyalinized, and there is adenomatous clumping of Leydig cells. Sertoli cells predominate. Azoospermia is characteristic, and infertility is the rule.

Management

Boys known to have Klinefelter syndrome should be monitored closely for speech, learning, and behavioral problems, and referred for early evaluation and treatment as needed. Testosterone, LH, and FSH levels should be checked at 11-12 yr of age and replacement therapy with a testosterone preparation is recommended once FSH and LH begin to rise above normal. Fasting glucose, lipids, and hemoglobin A_{1C} should also be obtained as these children are at risk for central adiposity and metabolic syndrome. A baseline dual-energy x-ray absorptiometry scan to assess bone density is also recommended by some authorities. Although testosterone treatment will normalize testosterone levels, stimulate the development of secondary sexual characteristics, increase bone mass and muscle mass, and improve body composition, it will *not* improve fertility (and will, in fact, suppress spermatogenesis). There is some evidence that it also improves mood and may have a positive effect on cognition and social functioning but the findings are not conclusive at this time. Either long-acting testosterone injections or daily application of testosterone gel may be used (testosterone patches have a high incidence of skin rash and are not frequently used in pediatrics). Testosterone enanthate or cypionate ester may be used in a starting dose of 25-50 mg injected intramuscularly every 3-4 wk, with 50-mg increments every 6-9 mo until a maintenance dose for adults (200-250 mg every 3-4 wk) is achieved. At that time, testosterone patches or testosterone gel may be substituted for the injections. Depending on patient and physician preference, transdermal testosterone may also be used as initial treatment instead of injections. For older boys, larger initial doses and increments can achieve more rapid virilization. The various transdermal preparations differ somewhat from each other and standard references should be consulted for recommendations regarding dosage and mode of application.

Gynecomastia may be treated with aromatase inhibitors (which will also increase endogenous testosterone levels) but medical treatment is not always successful and plastic surgery may be needed. Fertility is usually not an issue in the pediatric age group, but adults can father children using testicular sperm extraction followed by intracytoplasmic sperm injection. Because sperm counts decrease rapidly after onset of puberty in children with Klinefelter syndrome, sperm banking during early puberty is an option that can be discussed with a fertility specialist. Sperm counts can be stimulated using hCG treatment prior to testicular sperm extraction. Therapy, counseling and psychiatric services should be provided as needed for learning difficulties and psychosocial disabilities.

XX MALES

This disorder is thought to occur in 1 in 20,000 newborn males. Affected individuals have a male phenotype, small testes, a small phallus, and no evidence of ovarian or müllerian duct tissue. They appear, therefore, to be distinct from the ovotesticular disorder of sexual development. Undescended testes and hypospadias occur in a minority of patients. Infertility occurs in practically all cases and the histologic features of the testes are essentially the same as in Klinefelter syndrome. Patients with the condition usually come to medical attention in adult life because of hypogonadism, gynecomastia, or infertility. Hypergonadotropic hypogonadism occurs secondary to testicular failure. A few cases have been diagnosed perinatally as a result of discrepancies between prenatal ultrasonography and karyotype findings.

In 90% of XX males with normal male external genitalia, 1 of the X chromosomes carries the *SRY* (sex-determining region on the Y chromosome) gene. The exchange from the Y to the X chromosome occurs during paternal meiosis, when the short arms of the Y and X chromosomes pair. XX males inherit 1 maternal X chromosome and 1 paternal X chromosome containing the translocated male-determining gene. A few cases of 46,XX males with 9P translocations have also been identified. Most XX males who are identified before puberty have hypospadias or micropenis; this group of patients may lack Y-specific sequences, suggesting other mechanisms for virilization. Fluorescent in situ hybridization and primed in situ labeling have been used to identify small *SRY* DNA segments. Yp fragment abnormalities may result in sexually ambiguous phenotypes.

45,X MALES

In a few male patients recognized with a 45,X karyotype, Yp sequences are translocated to an autosomal chromosome. In 1 instance, the terminal short arm of the Y chromosome was translocated onto an X chromosome. In another, *SRY/autosomal* translocation was postulated. A male with 45,X karyotype and Leri-Weill dyschondrosteosis, *SHOX* gene loss, and SRY to Xp translocation also has been described.

47,XXX MALES

A Japanese male with poor pubic hair development, hypoplastic scrotal testes (4 mL), normal penis and normal height, gynecomastia, and severe cognitive impairment had 47,XXX karyotype caused by an abnormal X-Y interchange during paternal meiosis and X-X nondisjunction during maternal meiosis.

583.2 Hypogonadotropic Hypogonadism in the Male (Secondary Hypogonadism)

Omar Ali and Patricia A. Donohoue

In hypogonadotropic hypogonadism, lack of gonadal function is secondary to deficiency of 1 or both gonadotropins: FSH or LH. The primary defect may lie either in the anterior pituitary or in the hypothalamus. Hypothalamic etiologies result in deficiency of GnRH. The testes are normal but remain in the prepubertal state because stimulation by gonadotropins is lacking. The disorder may be recognized in infancy but is much more commonly recognized because of marked pubertal delay. Rarely, patients with an inherited form of hypogonadotropic hypogonadism (HH) may go through puberty and may present with hypogonadism as adults.

ETIOLOGY

HH may be genetic or acquired. Several different genes can cause inherited forms of HH; the affected genes may be upstream of GnRH, at the level of GnRH receptors, or at the level of gonadotropin production. In addition, various genetic defects in transcription factors such as POUF-1, LHX-3, LHX-4, and HESX-1 lead to defects in pituitary development and multiple pituitary hormone deficiencies, including deficiency of gonadotropins. Acquired pituitary gonadotropin deficiency may develop from various lesions in the hypothalamic-pituitary region (e.g., tumors, infiltrative disease, autoimmune disease, trauma, stroke).

Isolated Gonadotropin Deficiency

Isolated gonadotropin deficiency in which other pituitary hormone levels are normal is more likely to be from defects in the secretion of GnRH from the hypothalamus rather than defects in gonadotropin synthesis in the pituitary. It affects approximately 1 in 10,000 males and 1 in 50,000 females and encompasses a heterogeneous group of entities. Many cases are associated with anosmia and this combination of anosmia and HH defines Kallmann syndrome.

Kallmann syndrome is the most common form of HH and is genetically heterogeneous, with autosomal recessive, X-linked, and autosomal dominant forms of inheritance. Clinically, it is characterized by its association with **anosmia** or **hyposmia;** 85% of the cases are autosomal and 15% are X-linked. The X-linked form (KAL1) is caused by mutations of the *KAL1* gene at Xp22.3. This leads to failure of olfactory axons and GnRH-expressing neurons to migrate from their common origin in the olfactory placode to the brain. The *KAL* gene product anosmin-1, an extracellular 95 kDa matrix glycoprotein, facilitates neuronal growth and migration. The *KAL* gene is also expressed in various parts of the brain, facial mesenchyme, and mesonephros and metanephros, thus explaining some of the associated findings in patients with Kallmann syndrome, such as synkinesia (mirror movements), hearing loss, midfacial defects, and renal agenesis.

Some kindreds contain anosmic individuals with or without hypogonadism; others contain hypogonadal individuals who are anosmic.

Cleft lip and palate, hypotelorism, median facial clefts, sensorineural hearing loss, unilateral renal aplasia, neurologic deficits, and other findings occur in some affected patients. When Kallmann syndrome is caused by terminal or interstitial deletions of the Xp22.3 region, it may be associated with other contiguous gene syndromes, such as steroid sulfatase deficiency, chondrodysplasia punctata, X-linked ichthyosis, or ocular albinism.

The autosomal dominant form of Kallmann syndrome (KAL2) occurs in up to 10% of patients, and is caused by a loss of function mutation in the fibroblast growth factor receptor 1 *(FGFR1)* gene. Cleft lip and palate are associated with KAL2 but not with KAL1. Oligodontia and hearing loss may occur with both KAL1 and KAL2.

A variety of other genes, including *FGF8*, *PROK2/PROKR2*, *NELF*, *CHD7* (responsible for CHARGE [coloboma of the eye, heart anomaly, choanal atresia, retardation, and genital and ear anomalies] syndrome, which includes hypogonadism in its phenotype), *HS6ST1*, *WDR11*, and *SEMA3A*, are associated with defects in neuronal migration that can result in Kallmann syndrome, but in most patients the affected gene remains undefined.

Hypogonadotropic Hypogonadism Without Anosmia

A specific genetic defect is not found in most cases of normosmic idiopathic hypogonadotropic hypogonadism (IHH) but the list of genes associated with this disorder is growing; mutations in the genes *KISS1/KISS1R*, *TAC3/TACR3*, and*GNRH1/GNRHR* lead to abnormalities in the secretion and action of GnRH and are seen exclusively in patients with normosmic IHH. Mutations in *FGFR1*, *FGF8*, *PROKR2*, *CHD7*, and *WDR11* more commonly present with anosmia/hyposmia (Kallmann syndrome), but are also associated with normosmic IHH in some cases. It appears that kisspeptin (the gene product of the *KISS1* gene) and its G-protein–coupled receptor (GPCR54) play an important role in triggering puberty in humans and act downstream of the leptin receptor in this pathway. Rare cases of leptin deficiency and leptin receptor defects are also associated with HH. In addition, starvation and anorexia are associated with hypogonadism, most likely acting via the leptin pathway.

There are no known human mutations of the *GnRH* gene, but several families with mutations in the GnRH receptor have been described. These mutations account for 2-14% of idiopathic HH without anosmia. The severity of the defect is variable and many patients will respond to high-dose GnRH with increased gonadotropin secretion, indicating that the receptor defect is partial and not complete.

Mutations in gonadotropin genes are extremely rare. Mutations in the common α-subunit are not known in humans. Mutations in the LH-β subunit have been described in a few individuals and may lead to low, absent, or elevated LH levels, depending on the mutation. Defects in the FSH-β subunit may be the cause of azoospermia in a few rare cases.

Children with **X-linked congenital adrenal hypoplasia** have associated HH as a result of impaired GnRH secretion. In these patients, there is a mutation of the *DAX1* gene at Xp21.2-21.3. Conditions occasionally associated with these patients because of the **contiguous gene syndrome** include glycerol kinase deficiency, Duchenne muscular dystrophy, and ornithine transcarbamoyltransferase deficiency. Most boys with *DAX1* mutations develop HH in adolescence, although a patient with adult-onset adrenal insufficiency and partial HH and 2 females with HH and delayed puberty also have been described, the latter as part of extended families with males with classic HH. The *DAX1* gene defect is, however, rare in patients with delayed puberty or HH without at least a family history of adrenal failure (see Chapter 576).

It should be noted that genotype–phenotype correlations in IHH appear to be complex and pedigrees with digenic or oligogenic inheritance have been described. The same genetic defect may be associated with Kallmann syndrome, normosmic IHH, additional birth defects, delayed normal puberty, or an apparently normal phenotype. This variability has been observed more frequently in kindreds with mutations in *FGF8/FGFR1* and in *PROK2/PROKR2* ligand-receptor pairs, and may be from other interacting genes, epigenetic effects, or environmental factors.

Other Disorders with Hypogonadotropic Hypogonadism

HH has been observed in a few patients with polyglandular autoimmune syndrome, in some with elevated melatonin levels, and in those with a variety of other syndromes such as Bardet-Biedl, Prader-Willi, multiple lentigines, and several ataxia syndromes. In rare cases, HH is associated with complex chromosomal abnormalities.

Hypogonadotropic Hypogonadism Associated with Other Pituitary Hormone Deficiencies

Defects in pituitary transcription factors such as PROP-1, HESX-1, LHX-4, SOX-3, and LHX-3 lead to multiple pituitary deficiencies, including HH. Most of these present with multiple pituitary hormone deficiency in infancy, but some cases (especially with *PROP-1* mutations) may present with hypogonadism or hypoadrenalism in adult life. Growth hormone is almost always affected in multiple pituitary hormone deficiency, but thyroid-stimulating hormone and adrenocorticotropic hormone may be spared in some cases. In patients with organic lesions in or near the pituitary, the gonadotropin deficiency is usually pituitary in origin. Microphallus (<2.5 cm at term) in the newborn male with growth hormone deficiency suggests the possibility of gonadotropin deficiency.

DIAGNOSIS

Levels of gonadotropins and gonadal steroids are elevated for up to 6 mo after birth (minipuberty), and if the diagnosis of HH is suspected in early infancy these levels will be found to be inappropriately low. By the second half of the 1st yr of life these levels normally decline to near zero and remain suppressed until late childhood. Therefore, routine lab tests cannot distinguish HH from normal suppression of gonadotropins in this age group. At the normal age of puberty, these patients fail to show clinical signs of puberty or normal increase in LH and FSH levels. Children with constitutional delay of growth and puberty will have the same clinical picture and similar lab findings (and these cases are far more common than true HH, especially in males), and their differentiation from patients with HH is extremely difficult. Dynamic testing with GnRH or hCG may *not* be able to distinguish these groups in a reliable manner. A testosterone level greater than 50 ng/dL (1.7 nmol/L) generally indicates that normal puberty is likely, but a lower level does not reliably distinguish these groups. At least 1 study shows that an inhibin B level of <35 pg/mL in Tanner stage 1 and <65 pg/mL in Tanner stage 2 may be able to distinguish IHH from constitutional delay in males.

Insulin-like growth factor-1, thyroid-stimulating hormone, free thyroxine, and morning cortisol levels should be checked to assess the status of other anterior pituitary hormones; dynamic testing for growth hormone deficiency and adrenal insufficiency may be necessary if these are abnormal or equivocal. HH is very likely if the patient has evidence of another pituitary deficiency, such as a deficiency of growth hormone, particularly if it is associated with adrenocorticotropic hormone deficiency. **Hyperprolactinemia** is a known cause of delayed puberty and should be excluded by determination of serum prolactin levels in all patients. The presence of **anosmia** usually indicates permanent gonadotropin deficiency, but occasional instances of markedly delayed puberty (18-20 yr of age) have been observed in anosmic individuals. Although anosmia may be present in the family or in the patient from early childhood, its existence is rarely volunteered, and direct questioning is necessary in all patients with delayed puberty. Formal olfactometry, such as the University of Pennsylvania Smell Identification Test, is advisable to determine if partial degrees of hyposmia are present because IHH patients display a broad spectrum of olfactory function.

In the absence of family history, it may not be possible to make the diagnosis of HH with certainty, but the diagnosis will become more and more likely as puberty is delayed further beyond the normal age. If pubertal delay persists beyond age 18 yr with low 8 AM testosterone levels and inappropriately low gonadotropins (normal values are inappropriately low in this setting), then the patient can be presumptively diagnosed with HH. An MRI of the brain is indicated to look for

tumors and other anomalies in the hypothalamic-pituitary region. Genetic testing for pituitary transcription factors and several of the genes involved in isolated HH is also available and should be performed when possible. A renal ultrasound is recommended in patients with Kallmann syndrome because of its association with unilateral renal agenesis. Some authorities also recommend obtaining a baseline bone-density evaluation.

Treatment

Constitutional delay of puberty should be ruled out before a diagnosis of HH is established and treatment is initiated. Testicular volume of less than 4 mL by 14 yr of age occurs in approximately 3% of boys, but true HH is a rare condition. Even relatively moderate delays in sexual development and growth may result in significant psychologic distress and require attention. Initially, an explanation of the variations characteristic of puberty and reassurance suffice for the majority of boys. If by 15 yr of age no clinical evidence of puberty is beginning and the testosterone level is <50 ng/dL, a brief course of testosterone may be recommended. Various regimens are used, including testosterone enanthate 100 mg intramuscularly once monthly for 4-6 mo or 150 mg once monthly for 3 mo. Some practitioners use oral oxandrolone, which may have the theoretical advantage that it is not aromatized and may have less effect on bone age advancement (though definitive evidence of advantage is lacking). Oral oxandrolone may cause hepatic dysfunction and liver function tests should be monitored if it is used. Treatment is not necessary in all cases of constitutional delay, but if used, it is usually followed by normal progression through puberty and this may differentiate constitutional delay in puberty from isolated gonadotropin deficiency. The age of initiation of this treatment must be individualized.

Once a diagnosis of HH is made, treatment with testosterone will induce secondary sexual characteristics but will *not* stimulate testicular growth or spermatogenesis. Treatment with gonadotropins (either as a combination of hCG and human menopausal gonadotropins or using GnRH pulse therapy) will lead to testicular development, including spermatogenesis, but is much more complex to manage, so in most cases testosterone treatment is the best option. Either long-acting testosterone injections or daily application of testosterone gel may be used (testosterone patches have a high incidence of skin rash and are infrequently used in pediatrics). Testosterone enanthate or cypionate ester may be used in a starting dose of 25-50 mg injected intramuscularly every 3-4 wk, with 50 mg increments every 6-9 mo until a maintenance dose for adults (200-250 mg every 3-4 wk) is achieved. At that time, testosterone patches or testosterone gel may be substituted for the injections. Depending on patient and physician preference, transdermal testosterone may also be used as initial treatment instead of injections. For older boys, larger initial doses and increments can achieve more rapid virilization.

Treatment with gonadotropins is more physiologic but is expensive and complex, so it is less commonly used in adolescence. This treatment may be attempted in adult life when fertility is desired. The treatment schedule varies from 1,250-5,000 IU hCG in combination with 12.5-150 IU human menopausal gonadotropins 3 times per wk intramuscularly. It may require up to 2 yr of treatment to achieve adequate spermatogenesis in adults. Recombinantly produced gonadotropins (LH and FSH) are also able to stimulate gonadal growth and function but are much more expensive. Treatment with GnRH (when available) is the most physiologically appropriate, but it requires the use of a subcutaneous infusion pump to deliver appropriately pulsed therapy because continuous exposure to GnRH will suppress gonadotropins rather than stimulate them. In some cases, patients with GnRH defects also have pituitary or testicular dysfunction (a "dual defect") and may fail to respond adequately to GnRH or gonadotropin treatment. The rare patient with isolated LH deficiency can be treated effectively using hCG injections.

It has been found that up to 10% of patients diagnosed with HH (with or without anosmia) may exhibit spontaneous reversal of hypogonadism with sustained normal gonadal function when treatment has been discontinued; this may occur in patients with known genetic mutations in various genes, including *FGFR1*, *PROK2*, *GNRH*, *CHD7*, and *TAC/TACR3*. Such recovery is more likely in patients who show an increase in testicular volume during treatment or when treatment has been discontinued. Therefore, a brief trial of interruption of treatment is justified in patients with idiopathic HH. However, the recovery of gonadal function may not be lifelong.

Chapter 584

Pseudoprecocity Resulting from Tumors of the Testes

Omar Ali and Patricia A. Donohoue

Leydig cell tumors of the testes are rare causes of precocious pseudopuberty (gonadotropin-independent) and cause asymmetric enlargement of the testes. Leydig cells are sparse before puberty and tumors derived from them are more common in the adult, but rare cases do occur in children and the youngest reported case was in a 1 yr old boy. Although up to 10% of adult tumors may be malignant, metastasizing malignant tumors have not been reported in children, and pediatric Leydig cell tumors are usually unilateral and benign. Some tumors may be due to somatic activating mutations of the luteinizing hormone receptor.

The clinical manifestations are those of puberty in the male; onset usually occurs at 5-9 yr of age. Gynecomastia has been described. The tumor of the testis can usually be readily felt; the contralateral unaffected testis is normal in size for the age of the patient.

Plasma levels of testosterone are markedly elevated, and follicle-stimulating hormone and luteinizing hormone levels are suppressed. Ultrasonography may aid in the detection of small nonpalpable tumors. Fine-needle aspiration biopsy may help define the diagnosis.

Treatment consists of surgical removal of the affected testis. These tumors are generally resistant to chemotherapy. Progression of virilization ceases after removal of the tumor, and partial reversal of the signs of precocity may occur.

Testicular adrenal rests may develop into tumors that mimic Leydig cell tumors. Adrenal rest tumors are usually bilateral and occur in children with inadequately controlled congenital adrenal hyperplasia, usually of the salt-losing variety, during adolescence or young adult life. The stimulus for the growth of the adrenal rests is inadequate corticosteroid suppressive therapy causing excess adrenocorticotropic hormone secretion, and treatment with adequate doses almost always results in their regression. These tumors are histologically similar to primary Leydig cell tumors, but definite evidence of the origin of these may be achieved by demonstrating their 21-hydroxylase activity. Misdiagnosis of these tumors as primary Leydig cell tumors may lead to unnecessary orchidectomy and should be avoided.

Fragile X syndrome (see Chapter 81.5) is caused by the amplification of a polymorphic CGG repeat in the 5′ untranslated region of the *FMRI* gene at Xp17.3. The gene encodes an RNA binding protein that is highly expressed in the brain and the testis. In otherwise normal individuals, 6-50 CGG repeats are present in the gene; the presence of 50-200 repeats (permutation) is associated with mild intellectual disability and other abnormalities, and the presence of more than 200 repeats (fragile X mutation) is associated with the classic fragile X syndrome. Permutations are present in 1 in 1,000 white males, and

mutations are found in 1 in 4,000-8,000. A cardinal characteristic of the condition is testicular enlargement **(macroorchidism),** reaching 40-50 mL after puberty. Although the condition has been recognized in a child as young as 5 mo of age, affected boys younger than 6 yr of age rarely have testicular enlargement; by 8-10 yr of age, most have testicular volumes greater than 3 mL. The testes are enlarged bilaterally, are not nodular, and are histologically normal. Results of hormonal studies are normal. Direct DNA analysis searching for CGG repeat sequences permits definitive diagnosis.

Large-cell calcifying Sertoli cell tumors of the testes and **sex cord tumors with annular tubules** are extremely rare Sertoli cell tumors that may be a cause of breast development in young boys. These tumors are usually associated with Peutz-Jeghers syndrome or Carney complex; they often occur bilaterally, are multifocal, and are detectible by ultrasonography. Excessive production of aromatase (P450arom), the enzyme that converts testosterone to estradiol, causes feminization of these boys. Because they are usually benign, they may be left in place if they are not causing pain; the gynecomastia can be treated with aromatase inhibitors.

In boys with **unilateral cryptorchidism,** the contralateral testis is approximately 25% larger than normal for age. Testicular enlargement has also been noted in boys with Henoch-Schönlein purpura and lymphangiectasia. Epidermoid and dermoid cysts of the testes have been reported rarely.

Chapter 585
Gynecomastia

Omar Ali and Patricia A. Donohoue

Gynecomastia, the proliferation of mammary glandular tissue in the male, is a common condition. True gynecomastia (the presence of glandular breast tissue) needs to be distinguished from pseudogynecomastia, which is the result of accumulation of adipose tissue in the area of the breast that is commonly seen in overweight boys. True gynecomastia is characterized by the presence of a palpable fibroglandular mass at least 0.5 cm in diameter, located concentrically beneath the nipple and areolar region.

PHYSIOLOGIC FORMS OF GYNECOMASTIA

Gynecomastia occurs in many newborn males as a result of normal stimulation by maternal estrogen; the effect usually disappears in a few weeks. It is then extremely rare in prepubertal boys, in whom it should always be investigated to identify the cause, but again becomes common during normal puberty.

Neonatal Gynecomastia

Transient gynecomastia occurs in 60-90% of male newborns secondary to exposure to estrogens during pregnancy. Breast development may be asymmetrical and galactorrhea is seen in approximately 5%. Most cases resolve within 4-8 wk of birth, but a few can last as long as 12 mo.

Pubertal Gynecomastia

During early puberty to midpuberty, up to 70% of boys develop various degrees of subareolar hyperplasia of the breasts. Incidence peaks at 14 yr of age, at Tanner stage 3-4 and at a testicular volume of 5-10 mL. Physiologic pubertal gynecomastia may involve only 1 breast; it is not unusual for both breasts to enlarge at disproportionate rates or at different times. Tenderness of the breast is common but transitory. Spontaneous regression may occur within a few months; it rarely persists longer than 2 yr. Significant psychosocial distress may be present, especially in obese boys with relatively large breasts.

The cause is thought to be an imbalance between estrogen and androgen action at the level of breast tissue. Testing usually fails to reveal any significant difference in circulating estrogen and androgen levels between affected and unaffected males, but minor degrees of imbalance in free hormone levels may still be present. Other hormones, including leptin and luteinizing hormone, may directly stimulate breast development and may play a role in pubertal gynecomastia. Some cases may be caused by an increased sensitivity to estrogens and/or relative androgen resistance in the affected tissue. As androgen levels continue to rise in later puberty, most cases resolve.

Pathologic Gynecomastia

See Table 585-1.

Monogenic forms of gynecomastia are extremely rare, but do exist. Familial gynecomastia has occurred in several kindreds as an X-linked or autosomal dominant sex-limited trait. Some of these cases were found to be caused by constitutive activation of the P450 aromatase enzyme (*CYP19A1* gene), leading to increased peripheral conversion of C-19 steroids to estrogens (increased aromatization). A report of this syndrome in a father and his son and daughter suggests autosomal dominant inheritance. Excess aromatase activity was shown in skin fibroblasts and transformed lymphocytes in vitro.

Exogenous sources of estrogens are an important cause of gynecomastia in prepubertal children. Very small amounts of estrogens can cause gynecomastia in male children and accidental exposure may occur by inhalation, percutaneous absorption, or ingestion. Common sources of estrogens include oral contraceptive pills and oral and transdermal estrogen preparations. Gynecomastia has been reported in workers involved in the manufacture of estrogens and even in the children of such workers. Gynecomastia can also occur secondary to exposure to medications that decrease the level of androgens (especially free androgens), increase estradiol, or displace androgens from breast androgen receptors. Spironolactone, alkylating agents, anabolic steroids, human chorionic gonadotropin, ketoconazole, cimetidine, and androgen inhibitors such as flutamide are all associated with the occurrence of gynecomastia. Weaker associations are seen with a large number of other medications and drugs of abuse, including opiates, alcohol, and marijuana, although the association with marijuana may not be as strong as previously thought. Lavender, tea oils, and excessive consumption of soy are also implicated as causes of prepubertal gynecomastia.

Klinefelter syndrome and other causes of **male hypogonadism** are strongly associated with gynecomastia. Significant gynecomastia is seen in 50% of adolescents with Klinefelter syndrome; it is also seen in other conditions characterized by male undervirilization, including partial androgen insensitivity syndrome and 17-ketosteroid reductase deficiency. Gynecomastia has also been observed in children with congenital virilizing adrenal hyperplasia (11β-hydroxylase deficiency) and with Leydig cell tumors of the testis or with feminizing tumors of the adrenal gland. Several boys with Peutz-Jeghers syndrome and gynecomastia had sex cord tumors of the testes. The testes may not be enlarged in these cases and the tumor is usually multifocal and bilateral. Excessive aromatase production accounts for the gynecomastia. When gynecomastia is associated with galactorrhea, a prolactinoma should be considered. Hyperthyroidism alters the androgen to estrogen ratio by increasing bound androgen and decreasing the free testosterone and may result in gynecomastia in up to 40% of cases. Gynecomastia is also seen in malnourished patients after restoration of normal nutrition (refeeding syndrome), in whom it may be from hepatic dysfunction or abnormal activation of the gonadotropin axis.

EVALUATION OF GYNECOMASTIA

In pubertal cases a detailed history and physical examination may be all that is needed to exclude rare pathologic causes. Historical evaluation should include family history of male relatives with gynecomastia, history of liver or renal disease, use of medications or drugs of abuse, and exposure to herbal and cosmetic products that may contain phytoestrogens. Physical examination should include special attention to the breasts (looking for overlying skin changes, fixation, local lymphadenopathy, and nipple discharge) as well as a testicular exam. No

Table 585-1 Causes of Gynecomastia	
SYMPTOMS	**SIGNS**
FETAL ANDROGEN DEFICIENCY	
Ambiguous genitalia	Ambiguous genitalia (47,XY disorders of sex development) Normal female genitalia Microphallus (resembling clitoromegaly) Pseudovaginal perineoscrotal hypospadias Bifid scrotum Cryptorchidism
PREPUBERTAL ANDROGEN DEFICIENCY	
Delayed puberty	Eunuchoidism
Lack of sexual interest or desire (libido)	Infantile genitalia Small testes
Reduced nighttime or morning spontaneous erections	Lack of male hair pattern growth, no acne
Breast enlargement and tenderness	Disproportionately long arms and legs relative to height
Reduced motivation and initiative	Pubertal fat distribution Poorly developed muscle mass
Diminished strength and physical performance	High-pitched voice Reduced peak bone mass, osteopenia, or osteoporosis
No ejaculate or ejaculation (spermarche)	Gynecomastia
Inability to father children (infertility)	Small prostate gland Aspermia, severe oligozoospermia, or azoospermia
ADULT ANDROGEN DEFICIENCY	
Incomplete sexual development	Eunuchoidism
Lack of sexual interest or desire (libido)	Small or shrinking testes Loss of male hair (axillary and pubic hair)
Reduced nighttime or morning spontaneous erections	Gynecomastia
Breast enlargement and tenderness	Aspermia or azoospermia or severe oligozoospermia
Inability to father children (infertility)	Low bone mineral density (osteopenia or osteoporosis)
Height loss, history of minimal-trauma fracture	Height loss, minimal-trauma or vertebral compression fracture
Hot flushes, sweats	
Reduced shaving frequency	Unexplained reduction in prostate size or prostate-specific antigen
Less-Specific Symptoms	**Less-Specific Signs**
Decreased energy, vitality	Mild normocytic, normochromic anemia (normal female range)
Decreased motivation, self-confidence	Depressed mood, mild depression or dysthymia
Feeling sad or blue, irritability	Reduced muscle bulk and strength
Weakness, decreased physical or work performance	Increased body fat or body mass index
Poor concentration and memory	Fine facial skin wrinkling (lateral to orbits and mouth)
Increased sleepiness	

From Matsumoto AM, Bremner WJ: Testicular disorders. In Melmed S, Polonsky KS, Larsen PR, Kronenberg HM, editors: Williams textbook of endocrinology, *ed 12, Philadelphia, 2011, WB Saunders, Table 19-3, p. 719.*

laboratory evaluation is indicated in routine cases with no other associated abnormality but all prepubertal cases, as well as pubertal cases with suspicious features, should be investigated; initial laboratory evaluation should include thyroid function tests (to rule out hyperthyroidism), testosterone, estradiol, human chorionic gonadotropin, luteinizing hormone, and prolactin levels. Most cases of hyperprolactinemia are associated with galactorrhea, but there are a few reports of hyperprolactinemia causing gynecomastia without associated galactorrhea. Because of circadian variation, these levels should ideally be obtained in the morning. Other tests that may be indicated in selected cases include a karyotype, dehydroepiandrosterone sulfate, and liver and renal function tests. Gonadotropin levels may be a useful screen for Klinefelter syndrome and will be elevated in pubertal boys with this condition. If elevated, a karyotype should be performed.

TREATMENT

Treatment in case of benign pubertal gynecomastia usually consists of reassuring the boy and his family of the physiologic and transient nature of the phenomenon. When the enlargement is striking and persistent and causes serious emotional disturbance to the patient, specific treatment may be justified. Unfortunately, medical treatment is generally ineffective in long-standing cases. Early cases respond better to medical treatment but it is harder to justify treatment as most cases will resolve spontaneously. Agents that have been used for medical treatment include androgens, aromatase inhibitors, and estrogen antagonists. The effectiveness of synthetic androgens is variable and side effects are a concern, so these are rarely used in pediatrics. Aromatase inhibitors make physiologic sense, but placebo-controlled trials have been disappointing. Estrogen antagonists like tamoxifen and raloxifene are more effective, with raloxifene being the superior agent in at least 1 well-designed trial. If medical treatment is attempted, it should be in early cases (<12 mo standing) using raloxifene (in a dose of 60 mg/day) or tamoxifen (10-20 mg/day) for 3-9 mo, with the understanding that success rates are generally low in severe cases and mild cases will likely resolve on their own without treatment.

In those cases where breast development is excessive (Tanner stages 3-5), causes significant psychologic distress, and fails to regress in 18-24 mo, surgical removal of the enlarged breast tissue may be indicated, particularly in boys who have completed or nearly completed pubertal development. Careful examination and laboratory testing to exclude nonphysiologic causes are advisable before proceeding to surgery.

Chapter 586

Hypofunction of the Ovaries

Alvina R. Kansra and Patricia A. Donohoue

Hypofunction of the ovaries can be either primary or central in etiology. It may be caused by congenital failure of development, postnatal destruction (primary or hypergonadotropic hypogonadism), or lack of central stimulation by the pituitary and/or hypothalamus (secondary or tertiary hypogonadotropic hypogonadism). **Primary ovarian insufficiency** (hypergonadotropic hypogonadism), which is also termed *premature ovarian failure*, is characterized by the arrest of normal ovarian function before the age of 40 yr. Certain genetic mutations can result in primary ovarian insufficiency. Hypofunction of the ovaries because of a lack of central stimulation (hypogonadotropic hypogonadism) can be associated with other processes, such as multiple pituitary hormone deficiencies and some chronic diseases. Table 586-1 details the etiologic classification of ovarian hypofunction.

586.1 Hypergonadotropic Hypogonadism in the Female (Primary Hypogonadism)

Alvina R. Kansra and Patricia A. Donohoue

Diagnosis of hypergonadotropic hypogonadism before puberty is difficult. Except in the case of Turner syndrome, most affected patients have no prepubertal clinical manifestations.

Table 586-1 Etiologic Classification of Ovarian Hypofunction

HYPOGONADOTROPIC HYPOGONADISM

Hypothalamic

Genetic defects

- Kallmann syndrome *KAL1, FGFR1, FGF8, PROK2, PROKR2, CHD7, WDR11, NELF, SEMA3A*
- Other gene defects: leptin, leptin receptor, *KISS-1* (deficiency of kisspeptin), *DAX-1, TAC3* (deficiency of neurokinin B), *TACR3, SEMA7A*
- Inherited syndromes: Prader-Willi, Bardet-Biedl, and others
- Marked constitutional growth delay

Acquired defects (reversible)

- Anorexia nervosa
- Drug use
- Malnutrition
- Chronic illness, especially Crohn disease
- Hyperprolactinemia

Pituitary

Genetic defects

- Isolated gonadotropin deficiency (GnRH receptor, FSH, and LH β-subunit)
- Septooptic dysplasia (*HESX-1* in some cases)
- Disorders of pituitary organogenesis (*PROP1, LHX3, LHX4, SOX-3*, etc.)

Acquired defects

- Pituitary tumors
- Pituitary infarction
- Infiltrative disorders (histiocytosis, sarcoidosis)
- Hemosiderosis and hemochromatosis
- Radiation

HYPERGONADOTROPIC HYPOGONADISM

Genetic

Follicle-stimulating hormone and luteinizing hormone resistance
Mutations in steroidogenic pathways
46,XX gonadal dysgenesis
Turner syndrome and its variants
Noonan syndrome (*PTPN-11* gene)
SF-1 gene mutations
Galactosemia
Fragile X–associated disorders
Bloom syndrome
Werner syndrome
Ataxia-telangiectasia
Fanconi anemia

Acquired

Chemotherapy
Radiation
Autoimmune ovarian failure from autoimmune polyendocrine syndromes 1 and 2

TURNER SYNDROME

Turner described a syndrome consisting of sexual infantilism, webbed neck, and cubitus valgus in adult females (see Chapter 81). Ullrich described a girl with short stature and many of the same phenotypic features. The term *Ullrich-Turner syndrome* is frequently used in Europe, but is infrequently used in the United States where the condition is called Turner syndrome. The syndrome is defined as the combination of the characteristic phenotypic features accompanied by complete or partial absence of the second X chromosome with or without mosaicism.

Pathogenesis

Half the patients with Turner syndrome have a 45,X chromosomal complement. Approximately 15% of patients are mosaics for 45,X and a normal cell line (45,X/46,XX). Other mosaics with isochromosomes, 45,X/46,X,i(Xq); with rings, 45,X/46,X,r(X); or with fragments, 45,X/46fra, occur less often. Mosaicism is detected most commonly when more than 1 tissue is examined. The single X is of maternal origin in nearly 80% of 45,X patients. The mechanism of chromosome loss is unknown, and the risk for the syndrome does not increase with maternal age. The genes involved in the Turner phenotype are X-linked genes that escape inactivation. A major locus involved in the control of linear growth has been mapped within the pseudoautosomal region of the X chromosome (PAR1). *SHOX*, a homeobox-containing gene of 170 kb of DNA within the PAR1, is thought to be important for controlling growth in children with Turner syndrome, Leri-Weill syndrome, and, rarely, in patients having idiopathic short stature. Genes for the control of normal ovarian function are postulated to be on Xp and perhaps 2 "supergenes" on Xq.

Turner syndrome occurs in approximately 1 in 1,500-2,500 liveborn females. The frequency of the 45,X karyotype at *conception* is approximately 3%, but 99% of these are spontaneously aborted, accounting for 5-10% of all abortuses. Mosaicism (45,X/46,XX) occurs in a proportion higher than that seen with any other aneuploid state, but the mosaic Turner constitution is rare among the abortuses; these findings indicate preferential survival for mosaic forms.

The normal fetal ovary contains approximately 7 million oocytes, but these begin to disappear rapidly after the 5th mo of gestation. At birth, there are only 2 million (1 million active follicles); by menarche, there are 400,000-500,000; and at menopause, 10,000 remain. In the absence of 1 X chromosome, this process is accelerated, and nearly all oocytes are gone by 2 yr of age. In aborted 45,X fetuses, the number of primordial germ cells in the gonadal ridge appears to be normal, suggesting that the normal process is accelerated in patients with Turner syndrome. Eventually, the ovaries are described as "streaks" and consist only of connective tissue, with very few germ cells present.

Clinical Manifestations

Many patients with Turner syndrome are recognizable at birth because of a characteristic edema of the dorsa of the hands and feet and loose skinfolds at the nape of the neck. Low birthweight and decreased birth length are common (see Chapter 81). Clinical manifestations in childhood include webbing of the neck, a low posterior hairline, small mandible, prominent ears, epicanthal folds, high arched palate, a broad chest presenting the illusion of widely spaced nipples, cubitus valgus, and hyperconvex fingernails. The diagnosis is often first suspected at puberty when breast development fails to occur.

Short stature, the cardinal finding in virtually all girls with Turner syndrome, may be present with little in the way of other clinical manifestations. The linear growth deceleration begins in infancy and young childhood, gets progressively more pronounced in later childhood and adolescence, and results in significant adult short stature. Sexual maturation (breast development) fails to occur at the expected age; however, signs of adrenarche (pubic hair) are normally present. Among untreated patients with Turner syndrome, the mean adult height is 143-144 cm in the United States and most of northern Europe, but 140 cm in Argentina and 147 cm in Scandinavia (Fig. 586-1). The height is well correlated with the midparental height (average of the parents' heights). Specific growth curves for height have been developed for girls with Turner syndrome.

Associated **cardiac defects** are common. In the girls with Turner syndrome, life-threatening consequences of X-chromosome haploinsufficiency involve the cardiovascular system. There is a 4-5–fold increased rate of premature mortality secondary to congenital heart disease and premature coronary heart disease in adults with Turner syndrome. Clinically silent cardiac defects, mainly bicuspid aortic valve but also ascending aortic dilation, coarctation of the aorta, and partial anomalous pulmonary venous connections, are present in patients with Turner syndrome. Regardless of the age, all patients with Turner syndrome at the time of diagnosis need comprehensive cardiovascular evaluation by a cardiologist specializing in congenital heart disease. Complete cardiologic evaluation, including echocardiography, reveals isolated nonstenotic bicuspid aortic valves in one third to one half of patients. In later life, bicuspid aortic valve disease can progress to dilation of the aortic root. Less-frequent defects include aortic coarctation (20%), aortic stenosis, mitral valve prolapse, and anomalous pulmonary venous drainage. In 1 study, 38% of patients with 45,X chromosomes had cardiovascular malformations compared with 11%

Figure 586-1 Turner syndrome in a 15 yr old girl exhibiting failure of sexual maturation, short stature, cubitus valgus, and a goiter. There is no webbing of the neck. Karyotyping revealed 45,X/46,XX chromosome complement.

of those with mosaic monosomy X; the most common were aortic valve abnormalities and aortic coarctation. *Webbed neck in patients with or without recognized chromosome syndromes is associated with both flow-related and non–flow-related heart defects.* Among patients with Turner syndrome, those with webbed necks have a much greater chance of having coarctation of the aorta than do those without webbed necks. Transthoracic echocardiogram in young girls is adequate if cardiac anatomy is clearly seen; otherwise magnetic resonance angiographic screening studies should be considered in asymptomatic individuals with Turner syndrome. During adolescence, and certainly before pregnancy (when possible) is contemplated, repeat cardiac evaluation should be considered even in those without prior findings of cardiac abnormalities. Blood pressure should be routinely monitored even in the absence of cardiac or renal lesions and especially in those with suggestions of aortic root dilation. Cardiac MRI is a valuable tool to detect and monitor aortic root dilation.

Renal ultrasound should be performed in all girls with Turner syndrome at diagnosis. One fourth to one third of patients have **renal malformations** on ultrasonographic examination (50% of those with 45,X karyotypes). The more serious defects include pelvic kidney, horseshoe kidney, double collecting system, complete absence of 1 kidney, and ureteropelvic junction obstruction. Some of the malformations may increase the risk of hypertension and urinary tract infection. Idiopathic hypertension is also common. Girls with Turner syndrome who had normal baseline renal ultrasound findings did not develop renal disease during a follow-up period averaging 6 yr.

When the ovaries were examined by ultrasonography, older studies found a significant decrease in percentage of detectable ovaries from infancy to later childhood. A subsequent report found no such age-related differences in a cross-sectional and longitudinal study; 27-46% of patients had detectable ovaries at various ages; 76% of those with X mosaicism and 26% of those with 45,X karyotypes had detectable ovaries.

Sexual maturation usually fails to occur, but 10-20% of girls have spontaneous breast development, and a small percentage may have menstrual periods. Primary gonadal failure is associated with early onset of adrenarche (elevation in dehydroepiandrosterone sulfate) but delayed pubarche (pubic hair development). Spontaneous pregnancies have been reported in menstruating patients with Turner syndrome. Premature menopause, increased risk of miscarriage, and offspring with increased risk of trisomy 21 have been reported. A woman with a 45,X/46,X,r(X) karyotype treated with hormone replacement therapy had 3 pregnancies, resulting in a normal 46,XY male infant, a spontaneous abortion, and a healthy term female with Turner syndrome 45,X/46,Xr(X).

Antithyroid antibodies (thyroid peroxidase, and/or thyroglobulin antibodies) occur in 30-50% of patients. The prevalence increases with advancing age. **Autoimmune thyroid disease,** with or without the presence of a goiter, occurs in 10-30% of patients. Age-dependent abnormalities in carbohydrate metabolism characterized by abnormal glucose tolerance and insulin resistance and, only rarely, frank type 2 diabetes occur in older patients with Turner syndrome. Impaired insulin secretion has been described in 45,X women. Cholesterol levels are elevated in adolescence, regardless of body mass index or karyotype.

Inflammatory bowel disease, both Crohn disease and ulcerative colitis, gastrointestinal bleeding because of abnormal mesenteric vasculature, and delayed gastric emptying time have all been reported. Screening for celiac disease is recommended by recent guidelines, as the risk of celiac disease is increased in Turner syndrome, with 4-6% of individuals affected. Although autoimmune diseases have been associated with Turner syndrome, the prevalence of type 1 diabetes with Turner syndrome is not very high.

Sternal malformations can be detected by lateral chest radiography. An increased carrying angle at the elbow is usually not clinically significant. Scoliosis occurs in approximately 10% of adolescent girls. Congenital hip dysplasia occurs more commonly than in the general population. Reported eye findings include anterior segment dysgenesis and keratoconus. Pigmented nevi become more prominent with age; melanocytic nevi are common. Essential hyperhidrosis, torus mandibularis, and alopecia areata occur rarely.

Recurrent bilateral otitis media develops in approximately 75% of patients. Sensorineural hearing deficits are common, and the frequency increases with age. Problems with gross and fine motor-sensory integration, failure to walk before 15 mo of age, and early language dysfunction often raise questions about developmental delay, but intelligence is normal in most patients. However, cognitive impairment does occur in patients with 45,X/46,X,r(X); the ring chromosome is unable to undergo inactivation and leads to 2 functional X chromosomes.

Special attention should be given to psychosocial development in girls with Turner syndrome. In general, the behavior function is normal in girls with Turner syndrome, but they are at an increased risk for social isolation, immaturity, and anxiety. Other conditions, such as dyslexia, nonverbal learning disability, and attention deficit disorder, have been reported in girls with Turner syndrome. In adults, deficits in perceptual spatial skills are more common than they are in the general population. Some unconfirmed data suggest the existence of an imprinted X-linked locus that affects cognitive function such as verbal and higher-order executive function skills. These functions are apparently better when the X is paternal in origin.

The prevalence of mosaicism depends in large part on the techniques used for studying chromosomal patterns. The use of fluorescent in situ hybridization and reverse transcription–polymerase chain reaction (PCR) has increased the reported prevalence of mosaic patterns to as high as 60-74%.

Mosaicism involving the Y chromosome occurs in 5%. A population study using PCR with 5 different primer sets found Y chromosome material in 12.2%. **Gonadoblastoma** among Y-positive patients occurred in 7-10%. Therefore, the recommendation is that prophylactic gonadectomy should be performed even in the absence of MRI or CT evidence of tumors. The recommended timing of this procedure is

at the time of diagnosis, but this may need to be reevaluated in the future. The gonadoblastoma locus on the Y chromosome (GBY) maps close to the Y centromere. The presence of only the SRY (sex-determining region on the Y chromosome) locus is not sufficient to confer increased susceptibility for the development of gonadoblastoma. A detailed study of 53 patients with Turner syndrome by nested PCR excluded low-level Y mosaicism in almost all cases. A second round of PCR detected SRY on the distal short arm of the Y chromosome in only 2 subjects. Therefore, routine PCR for Y chromosome detection for the purpose of assigning gonadoblastoma risk is not indicated. High-throughput quantitative genotyping may provide an effective and inexpensive method for the identification of X chromosome abnormalities and Y chromosome material identification.

In patients with 45,X/46,XX mosaicism, the clinical abnormalities are attenuated and fewer; short stature is as frequent as it is in the 45,X patient and may be the only manifestation of the condition other than ovarian failure (see Fig. 586-1).

Laboratory Findings

Chromosomal analysis must be considered routinely in short girls. In a systematic search, using Southern blot analysis of leukocyte DNA, Turner syndrome was detected in 4.8% of girls referred to an endocrinology service because of short stature. Patients with a marker chromosome in some or all cells should be tested for DNA sequences at or near the centromere of the Y chromosome for GBY.

Ultrasonography of the heart, kidneys, and ovaries is indicated after the diagnosis is established. The most common skeletal abnormalities are shortening of the 4th metatarsal and metacarpal bones, epiphyseal dysgenesis in the joints of the knees and elbows, Madelung deformity, scoliosis, and in older patients, inadequate osseous mineralization.

Plasma levels of gonadotropins, particularly follicle-stimulating hormone (FSH), are markedly elevated to greater than those of age-matched controls during infancy; at 2-3 yr of age, a progressive decrease in levels occurs until they reach a nadir at 6-8 yr of age, and by 10-11 yr of age, they rise to adult castrate levels.

Antithyroid peroxidase and antithyroglobulin antibodies should be checked periodically, and if positive, levels of thyroxine and thyroid-stimulating hormone should be obtained. Turner syndrome girls should be screened for **celiac disease** by measuring tissue transglutaminase immunoglobulin A antibodies. Initial testing should be done around age 4 yr and repeated every 2-5 yr. Extensive studies have failed to establish that growth hormone deficiency plays a primary role in the pathogenesis of the growth disorder. Defects in normal secretory patterns of growth hormone are seen in adolescents because of a lack of gonadal steroids, but not in younger girls with Turner syndrome. In vitro, monocytes and lymphocytes show decreased sensitivity to insulin-like growth factor 1.

Treatment

Treatment with recombinant human growth hormone increases height velocity and ultimate stature in most, but not all, children with Turner syndrome. Many girls achieve heights of greater than 150 cm with early initiation of treatment. In a large, multicenter, placebo-controlled clinical trial, 99 patients with Turner syndrome who started receiving growth hormone at a mean age of 10.9 yr at doses between 0.27 and 0.36 mg/kg/wk achieved a mean height of 149 cm, with nearly one third reaching heights greater than 152.4 cm (60 in). In the Netherlands, higher doses of growth hormone (up to 0.63 mg/kg/wk in the 3rd yr of treatment) resulted in 85% of the subjects reaching adult heights in the normal range for the Dutch reference population. Growth hormone treatment should be initiated in early childhood and/or when there is evidence of height velocity attenuation on specific Turner syndrome growth curves. The average starting dose of growth hormone is 0.375 mg/kg/wk. Growth hormone therapy does not significantly aggravate carbohydrate tolerance and does not result in marked adverse events in patients with Turner syndrome. Serum levels of insulin-like growth factor 1 should be monitored if the patient is receiving high doses of growth hormone. If the insulin-like growth factor 1 levels are significantly elevated, the dose of growth hormone may need to be reduced. Treatment with growth hormone can cause excessive growth of the hands and feet in some girls with Turner syndrome.

Oxandrolone has also been used to treat the short stature associated with Turner syndrome, either alone or in combination with growth hormone. This synthetic anabolic steroid has weak androgenic effects, and patients should be monitored for signs of pubarche, as well as hepatotoxicity. The latter is rare.

Replacement therapy with estrogens is indicated, but there is little consensus about the optimal age at which to initiate treatment. The psychologic preparedness of the patient to accept therapy must be taken into account. The improved growth achieved by girls treated with growth hormone in childhood permits initiation of estrogen replacement at 12-13 yr. Delaying estrogen therapy to optimize height potential until 15 yr of age, as previously recommended, seems unwarranted. This change to starting earlier estrogen therapy was considered because of the psychologic importance of age-appropriate pubertal maturation. Also, delaying estrogen therapy could be deleterious for bone health and other aspects of the child's health. Low-dose estrogen replacement at 12 yr of age permits a normal pace of puberty without interfering with the positive effect of growth hormone on the final adult height. Estrogen therapy improves verbal and nonverbal memory in girls with Turner syndrome. In young women with age-appropriate pubertal development who achieve normal height, health-related quality-of-life questionnaires have yielded normal results.

Although many forms of estrogen are available, oral estrogens have been mostly used. Even though transdermal and injectable depot forms of estradiol may be alternative physiologic options, transdermal patches are increasing in popularity. This is because transdermal patches bypass the first hepatic metabolism, thereby requiring only a small amount of estrogen to attain the adequate levels for its function. For oral preparation a conjugated estrogen (Premarin), 0.15-0.625 mg daily, or micronized estradiol (Estrace), 0.5 mg given daily for 3-6 mo, is usually effective in inducing puberty. The recommendations for transdermal patch are 6.25 µg daily that is gradually increased over 2 yr to the adult dose of 100-200 µg daily. The estrogen then is cycled (taken on days 1-23) and a progestin (Provera) is added (taken on days 10-23) in a dose of 5-10 mg daily. In the remainder of the calendar month, during which no treatment is given, withdrawal bleeding usually occurs.

Prenatal chromosome analysis for advanced maternal age has revealed a frequency of 45,X/46,XX that is 10 times higher than when diagnosed postnatally. Most of these patients have no clinical manifestations of Turner syndrome, and levels of gonadotropins are normal. Awareness of this mild phenotype is important in counseling patients.

Psychosocial support for these girls is an integral component of treatment. A comprehensive psychologic education evaluation is recommended either at the time of Turner syndrome diagnosis, depending on the patient's age, when any of the components of behavior or cognition become obvious, or immediately preceding school entry. The Turner Syndrome Society, which has local chapters in the United States, and similar groups in Canada and other countries provide a valuable support system for these patients and their families in addition to that given by the healthcare team.

Successful pregnancies have been carried to term using ovum donation and in vitro fertilization. Adolescents with few signs of spontaneous puberty may have ovaries with follicles. There remains a future possibility of using cryopreserved ovarian tissue with immature oocytes before the regression of the ovaries for the future pregnancies. In adult women with Turner syndrome, there seems to be a high prevalence of undiagnosed bone mineral density, lipid, and thyroid abnormalities. Glucose intolerance, diminished 1st-phase insulin response, elevated blood pressure, and lowered fat-free mass are common. Glucose tolerance worsens, but fat-free mass and blood pressure and general physical fitness improve with sex hormone replacement. The neurocognitive profile of adult women is unaffected by estrogen status.

XX GONADAL DYSGENESIS

Some phenotypically and genetically normal females have gonadal lesions identical to those in 45,X patients but without somatic features

of Turner syndrome; their condition is termed **pure gonadal dysgenesis** or **pure ovarian dysgenesis**.

The disorder is rarely recognized in prepubertal children because the external genitals are normal, no other abnormalities are visible, and growth is normal. At pubertal age, sexual maturation fails to take place. Plasma gonadotropin levels are elevated. Delay of epiphyseal fusion may result in a **eunuchoid** habitus. Pelvic ultrasonography reveals streak ovaries.

Affected siblings, parental consanguinity, and failure to uncover mosaicism all point to female-limited autosomal recessive inheritance. The disorder appears to be especially frequent in Finland (1 in 8,300 liveborn girls). In this population, several mutations in the FSH receptor gene (on chromosome 2p) were demonstrated as the cause of the condition. FSH receptor gene mutations were not detected in Mexican women with 46,XX gonadal dysgenesis. In some patients, XX gonadal dysgenesis has been associated with sensorineural deafness (**Perrault syndrome**). A patient with this condition and concomitant growth hormone deficiency and virilization has also been reported. There may be distinct genetic forms of this disorder. **Müllerian agenesis,** or the **Mayer-Rokitansky-Küster-Hauser** syndrome, which is second to gonadal dysgenesis as the most common cause of primary amenorrhea, occurring in 1 in 4,000-5,000 females, has been reported in association with 46,XX gonadal dysgenesis in a 17 yr old adolescent with primary amenorrhea and lack of breast development. One case of dysgerminoma with syncytiotrophoblastic giant cells was reported. An 18 yr old woman with primary amenorrhea and an absence of müllerian-derived structures, unilateral renal agenesis, and clinical signs of androgen excess, a phenotype resembling the Mayer-Rokitansky-Küster-Hauser syndrome, was found to have a loss-of-function mutation in the *WNT4* gene. Treatment consists of estrogen replacement therapy.

45,X/46,XY GONADAL DYSGENESIS

45,X/46,XY gonadal dysgenesis, also called **mixed gonadal dysgenesis,** has extreme phenotypic variability postnatally that may extend from a Turner-like syndrome to a male phenotype with a penile urethra; it is possible to delineate 3 major clinical phenotypes. Short stature is a major finding in all affected children. Ninety percent of prenatally diagnosed cases have a normal male phenotype.

Some patients have no evidence of virilization; they have a female phenotype and often have the somatic signs of Turner syndrome. The condition is discovered prepubertally when chromosomal studies are made in short girls, or later when chromosomal studies are made because of failure of sexual maturation. Fallopian tubes and uterus are present. The gonads consist of intraabdominal undifferentiated streaks; chromosomal study of the streak often reveals an XY cell line. The streak gonad differs somewhat from that in girls with Turner syndrome; in addition to wavy connective tissue, there are often tubular or cordlike structures, occasional clumps of granulosa cells, and frequently, mesonephric or hilar cells.

Some children have mild virilization manifested only by prepubertal clitoromegaly. Normal müllerian structures are present, but at puberty virilization occurs. These patients usually have an intraabdominal testis, a contralateral streak gonad, and bilateral fallopian tubes.

Many 45,X/46,XY children present with frank ambiguity of the genitals in infancy. A testis and vas deferens are found on one side in the labioscrotal fold, and a streak gonad is identified on the contralateral side. Despite the presence of a testis, fallopian tubes are often present bilaterally. An infantile or rudimentary uterus is almost always present.

Other genotypes and phenotypes have been described in mixed gonadal dysgenesis. Approximately 25% of 200 analyzed patients have a dicentric Y chromosome (45,X/46,X,dic Y). In some patients, the Y chromosome may be represented by only a fragment (45,X/45,X +fra); application of Y-specific probes can establish the origin of the fragment. It is not clear why the same genotype (45,X/46,XY) can result in such diverse phenotypes. Mutations in the *SRY* gene have been described in some patients.

Children with a female phenotype present no problem in gender of rearing. Patients who are only slightly virilized are usually assigned a female gender of rearing before a diagnosis is established. Patients with ambiguity of the genitals are readily often clinically indistinguishable from patients with various types of 46,XY disorders of sex development (46,XY DSD). In some instances, there may need to be careful consideration regarding sex of rearing. Factors that may influence this decision include short stature, the need for surgical genital reconstruction, the presence of müllerian structures, and the need for gonadectomy because of predisposition of the gonad to the development of malignancy. In some patients followed to adulthood, the putative normal testis proves to be dysgenetic with eventual loss of Leydig and Sertoli cell function (see Chapter 583). In an analysis of 22 patients with mixed gonadal dysgenesis, no significant associations or correlations were found between internal and external phenotypes or endocrine function and gonadal morphologic features. The sex of rearing was determined by the appearance of the external genitalia. In 11 patients, basal and human chorionic gonadotropin–stimulated testosterone levels were lower than in control subjects.

Gonadal tumors, usually **gonadoblastomas,** occur in approximately 25% of these children. As described above, a gonadoblastoma locus has been localized to a region near the centromere of the Y chromosome (GBY). These germ cell tumors are preceded by the changes of carcinoma in situ. Accordingly, both gonads should be removed in all patients reared as girls, and the undifferentiated gonad should be removed in the patients reared as boys.

There is no correlation among the proportion of 45,X/46,XY cell lines in either blood or fibroblasts with the phenotype. In the past, all patients came to clinical attention because of their abnormal phenotypes. However, 45,X/46,XY mosaicism is found in approximately 7% of fetuses, with true chromosome mosaicism encountered prenatally. Of 76 infants with 45,X/46,XY mosaicism diagnosed prenatally, 72 had a normal male phenotype, 1 had a female phenotype, and only 3 males had hypospadias. Of 12 males whose gonads were examined, only 3 were abnormal. These data must be taken into account when counseling a family in which a 45,X/46,XY infant is discovered prenatally.

XXX, XXXX, AND XXXXX FEMALES

XXX Females

The 47,XXX (trisomy) chromosomal constitution is the most frequent extra–X chromosome abnormality in females, occurring in almost 1 in 1,000 liveborn females. In 68%, this condition is caused by maternal meiotic nondisjunction, but most 45,X and half of 47,XXY constitutions are caused by paternal sex chromosome errors. The phenotype is that of a normal female; affected infants and children are not recognized based on the genital appearance.

Sexual development and menarche are normal. Most pregnancies have resulted in normal infants. By 2 yr of age, delays in speech and language become evident and lack of coordination, poor academic performance, and immature behavior are seen in some. These girls tend to be tall and gangly, manifest behavior disorders, and are placed in special education classes. Using high-resolution MRI, 10 47,XXX subjects had lower amygdala volumes than 20 euploid controls; 10 47,XXY subjects had even lower amygdala volumes. In a review of 155 girls, 62% were physically normal. There is marked variability within the syndrome, and a small proportion of affected girls are well coordinated, socially outgoing, and academically superior.

XXXX and XXXXX Females

The great majority of females with these rare karyotypes have been intellectually challenged. Commonly associated defects are epicanthal folds, hypertelorism, clinodactyly, transverse palmar creases, radioulnar synostosis, and congenital heart disease. Sexual maturation is often incomplete and may not occur at all. Nevertheless, 3 women with the tetra-X syndrome gave birth, but no pregnancies were reported in 49,XXXXX women. Most 48,XXXX women tend to be tall, with an average height of 169 cm, whereas short stature is a common feature of the 49,XXXXX phenotype.

NOONAN SYNDROME

Girls with Noonan syndrome show certain anomalies that also occur in girls with 45,X Turner syndrome, but they have normal 46,XX chromosomes (see Chapter 81.4). The most common abnormalities are

the same as those described for males with Noonan syndrome (see Chapter 583.1). Short stature is one of the cardinal signs of this syndrome. The phenotype differs from Turner syndrome in several respects. Cognitive impairment is often present, the cardiac defect is most often pulmonary valvular stenosis or an atrial septal defect rather than an aortic defect, normal sexual maturation usually occurs but is delayed by 2 yr on average, and premature ovarian failure has been reported. Growth hormone therapy is approved by the FDA for use in Noonan syndrome patients with short stature.

OTHER OVARIAN DEFECTS

Some young women with no chromosomal abnormality are found to have streak gonads that may contain only occasional or no germ cells. Gonadotropins are increased. Cytotoxic drugs, especially alkylating agents such as cyclophosphamide and busulfan, procarbazine, etoposide, and exposure of the ovaries to irradiation for the treatment of malignancy are frequent causes of ovarian failure. Young women with Hodgkin disease demonstrate that combination chemotherapy and pelvic irradiation may be more deleterious than either therapy alone. Teenagers are more likely than older women to retain or recover ovarian function after irradiation or combined chemotherapy; normal pregnancies have occurred after such treatment. Treatment regimens may result in some ovarian damage in most girls treated for cancer. The median lethal dose for the human oocyte is estimated to be approximately 4 Gy; doses as low as 6 Gy have produced primary amenorrhea. Ovarian transposition before abdominal and pelvic irradiation in childhood can preserve ovarian function by decreasing the ovarian exposure to less than 4-7 Gy.

Autoimmune ovarian failure occurs in 60% of children older than 13 yr of age with type I autoimmune polyendocrinopathy (Addison disease, hypoparathyroidism, candidiasis). This condition, also known as *polyglandular autoimmune disease* type 1 is rare worldwide but not in Finland, where, as a result of a founder gene effect, it occurs in 1 in 25,000 people. The gene for this disorder is located on chromosome 21 and is associated with human leukocyte antigen (HLA) DR5. In patients with polyglandular autoimmune disease type 1 and ovarian failure, an association with HLA-A3 has been described. Affected girls may not develop sexually, or secondary amenorrhea may occur in young women. The ovaries may have lymphocytic infiltration or appear simply as streaks. Most affected patients have circulating steroid cell antibodies and autoantibodies to 21-hydroxylase. Among patients with polyglandular autoimmune syndromes, 5% were found to have hypogonadism.

The condition also occurs in young women as an isolated event or in association with other autoimmune disorders, leading to secondary amenorrhea (premature ovarian failure [POF]). It occurs in 0.2-0.9% of women younger than 40 yr of age. Premature ovarian failure is a heterogeneous disorder with many causes: chromosomal, genetic, enzymatic, infectious, and iatrogenic. When associated with autoimmune adrenal disease, steroid cell autoantibodies are always present. These antibodies react with P450scc, 17α-OH, or 21-OH enzymes. When associated with an entire host of endocrine and nonendocrine autoimmune diseases and not adrenal autoimmunity, steroid cell autoantibodies are rarely found. A second autoimmune disorder, often subclinical, is found in 10-39% of adult patients with POF. One 17 yr old with idiopathic thrombocytopenic purpura and 47,XXX chromosomes had autoimmune POF. Patients with POF do not have the neurocognitive defects found in Turner syndrome patients.

Galactosemia, particularly the classical form of the disease, usually results in ovarian damage, beginning during intrauterine life. Levels of FSH and luteinizing hormone (LH) are elevated early in life. Ovarian damage may be caused by deficient uridine diphosphate-galactose (see Chapter 87). The **Denys-Drash syndrome,** caused by a *WT1* mutation, can result in ovarian dysgenesis.

Ataxia-telangiectasia may be associated with ovarian hypoplasia and elevated gonadotropins; the cause is unknown. Gonadoblastomas and dysgerminomas have occurred in a few girls.

Hypergonadotropic hypogonadism has been postulated to also occur because of the resistance of the ovary to both endogenous and exogenous gonadotropins (Savage syndrome). This condition occurs also in women with POF. Antiovarian antibodies or FSH receptor abnormalities may cause this condition. Mutation of the FSH receptor gene has been reported as an autosomal recessive condition (see Chapter 582). A few females with 46,XX chromosomes presenting in primary amenorrhea with elevated gonadotropin levels were found to have inactivating mutations of the LH receptor gene. This suggests that LH action is needed for normal follicular development and ovulation. Other genetic defects associated with ovarian failure include mutations in *FOXL2, GNAS, CYP17,* and *CYP19.* Some data also suggest that mutations within the gene encoding transcription factor SF-1 are associated with early ovarian failure.

586.2 Hypogonadotropic Hypogonadism in the Female (Secondary Hypogonadism)

Alvina R. Kansra and Patricia A. Donohoue

Hypofunction of the ovaries can result from failure to secrete normal pulses of the gonadotropins LH (luteinizing hormone) and FSH. Hypogonadotropic hypogonadism may occur if the hypothalamic-pituitary-gonadal axis is interrupted either at the hypothalamic or pituitary level. The mechanisms that result in hypogonadotropic hypogonadism include failure of the hypothalamic luteinizing hormone–releasing hormone (also known as *gonadotropin-releasing hormone*) pulse generator or inability of the pituitary to respond with secretion of LH and FSH. It is often difficult to distinguish between marked constitutional delay and hypogonadotropic hypogonadism.

ETIOLOGY

Hypopituitarism

Hypogonadotropic hypogonadism is most commonly seen with multiple pituitary hormone deficiencies resulting from malformations (e.g., septooptic dysplasia, other midline defects), pituitary transcription factor defects such as in PROP-1, or lesions of the pituitary that are acquired postnatally. Familial isolated gonadotropin deficiency associated with anosmia (Kallmann syndrome) was described in 1944. Many other genetic causes for hypogonadotropic hypogonadism have been identified. A gene important in luteinizing hormone–releasing hormone secretion is named *KISS* (encoding the protein kisspeptin), which is suggested to play a significant role in the development of the luteinizing hormone–releasing hormone–secreting cells. Another set of genes recently implicated in hypogonadotropic hypogonadism are the genes for neurokinin B *(TAC3)* and its receptor *(TAC3R).*

In children with idiopathic hypopituitarism, the defect is usually found in the hypothalamus. In these patients, administration of gonadotropin-releasing hormone results in increased plasma levels of FSH and LH, establishing the integrity of the pituitary gland.

Hypogonadotropic hypogonadism is less common than hypergonadotropic hypogonadism. The latter condition, when associated with LH excess, underlies polycystic ovarian syndrome (Stein-Leventhal syndrome; see Chapter 552).

Isolated Deficiency of Gonadotropins

This heterogeneous group of disorders is characterized more fully with the use of the gonadotropin-releasing hormone analog stimulation test. In most children, the pituitary gland is normal, and the defect causing gonadotropin deficiency resides in the hypothalamus. Patients with hyperprolactinemia, most often caused by a pituitary prolactin-secreting adenoma, often have suppression of gonadotropin secretion. If breast development has occurred, then galactorrhea and amenorrhea are frequently seen.

Several sporadic instances of anosmia with hypogonadotropic hypogonadism have been reported. **Anosmic** hypogonadal females have

also been reported in kindreds with Kallmann syndrome, but hypogonadism more frequently affects the males in these families. Mutations in the gene for the β-subunit of FSH and LH have been reported.

Some autosomal recessive disorders, such as the Laurence-Moon-Biedl, multiple lentigines, and Carpenter syndromes, appear in some instances to include gonadotropic hormone deficiency. Patients with Prader-Willi syndrome usually have some degree of hypogonadotropic hypogonadism. Girls with severe thalassemia may have gonadotropin deficiency from pituitary damage caused by chronic iron overload secondary to multiple transfusions. Anorexia nervosa frequently results in hypogonadotropic hypogonadism. The rare patients described with leptin deficiency or leptin receptor defects have failure of pubertal maturation because of gonadotropin deficiency.

DIAGNOSIS

The diagnosis may be apparent in patients with other deficiencies of pituitary tropic hormones, but, as in males, it is difficult to differentiate isolated hypogonadotropic hypogonadism from physiologic delay of puberty. Repeated measurements of FSH and LH, particularly during sleep, may reveal the rising levels that herald the onset of puberty. Stimulation testing with gonadotropin-releasing hormone or one of its analogs may help establish the diagnosis. Morbidity for both men and women with hypogonadism includes infertility and an increased risk of osteoporosis.

Chapter 587

Pseudoprecocity Resulting from Lesions of the Ovary

Alvina R. Kansra and Patricia A. Donohoue

Girls with signs of early puberty may, in rare circumstances, have a lesion of the ovary as the etiology. These include tumors or cysts that secrete estrogenic, androgenic, or both types of hormones. In these patients the sex steroid production is not mediated by pituitary gonadotropin secretion, and thus they are said to produce pseudoprecocity.

Ovarian tumors are rare in the pediatric population, occurring at a rate of less than 3 in 100,000. Most ovarian masses are benign, but 10-30% may be malignant. If they occur before 8 yr of age they may cause signs of puberty. Ovarian malignancies, the most common genital neoplasms in adolescence, account for only 1% of childhood cancers. More than 60% are germ cell tumors, most of which are dysgerminomas that can secrete tumor markers as well as sex hormones (see Chapter 503). Five to 10% of germ cell tumors occur in phenotypic females with abnormal gonads associated with the presence of a Y chromosome. Next most common are epithelial cell tumors (20%), and nearly 10% are sex cord/stromal tumors (granulosa, Sertoli cell, and mesenchymal tumors). Multiple tumor markers can be seen in ovarian tumors, including α-fetoprotein, human chorionic gonadotropin, carcinoembryonic antigen, oncoproteins, p105, p53, *KRAS* mutations, cyclin D_1, epidermal growth factor–related proteins and receptors, cathepsin B, and others. Variable levels of inhibin–activin subunit gene expression have been detected in ovarian tumors.

Functioning lesions of the ovary consist of benign cysts or malignant tumors. The majority synthesize estrogens; a few synthesize androgens. The most common estrogen-producing ovarian tumor causing precocious puberty is the granulosa cell tumor. Other tumors that can cause precocious puberty are thecomas, luteomas, mixed types, theca-lutein and follicular cysts, and ovarian tumors (i.e., teratoma, choriocarcinoma, and dysgerminoma).

ESTROGENIC LESIONS OF THE OVARY

These lesions cause isosexual precocious sexual development but account for only a small percentage of all cases of precocity. Benign ovarian follicular cysts are the most common tumors associated with isosexual precocious puberty in girls; they may rarely be gonadotropin dependent. Gonadotropin-independent follicular cysts that produce estrogen are often associated with the McCune-Albright syndrome.

Juvenile Granulosa Cell Tumor

In childhood, the most common neoplasm of the ovary with estrogenic manifestations is the granulosa cell tumor, although it makes up only 1-10% of all ovarian tumors. These tumors have distinctive histologic features that differ from those encountered in older women (adult granulosa cell tumor). The cells have high mitotic activity, follicles are often irregular, Call-Exner bodies are rare, and luteinization is frequent. The tumor may be solid or cystic, or both. It usually is benign. In a few instances, this tumor has been associated with multiple enchondromas **(Ollier disease)** and, in fewer still, with multiple subcutaneous hemangiomas **(Maffucci syndrome).**

Clinical Manifestations and Diagnosis

The juvenile granulosa cell tumor has been observed in newborns and may manifest with sexual precocity at 2 yr of age or younger; about half these tumors occurred before 10 yr of age. The mean age at diagnosis is 7.5 yr. The tumors are almost always unilateral. The breasts become enlarged, rounded, and firm, and the nipples prominent. The external genitals resemble those of a normal girl at puberty, and the uterus is enlarged. A white vaginal discharge is followed by irregular or cyclic menstruation. Ovulation, however, does not occur. The presenting manifestation may be abdominal pain or swelling. Pubic hair is usually absent unless there is mild virilization.

A mass is readily palpable in the lower portion of the abdomen in most children by the time sexual precocity is evident. The tumor may be small, however, and escape detection even on careful rectal and abdominal examination; the tumors may be detected by ultrasonography, but multidetector CT scans are most sensitive. Most such tumors (90%) are diagnosed at very early stages of malignancy.

Plasma estradiol levels are markedly elevated. Plasma levels of gonadotropins are suppressed and do not respond to gonadotropin-releasing hormone analog stimulation. Levels of antimüllerian hormone, inhibin B, and α-fetoprotein may be elevated. Activating mutations of $G_S\alpha$ are seen in 30%, and GATA-4 expression is retained in the more aggressive tumors while antimüllerian hormone levels are inversely proportional to tumor size. Osseous development is moderately advanced. Several case reports showing the association of 45,X/46,XY karyotype and ambiguous genitalia with ovarian granulosa tumor have been published in literature.

Treatment and Prognosis

The tumor should be removed as soon as the diagnosis is established. Prognosis is excellent because fewer than 5% of these tumors in children are malignant. Advanced-stage tumors, however, behave aggressively and require difficult decisions regarding surgical approaches as well as the use of irradiation and chemotherapy. In adults with granulosa cell tumors, p53 expression is associated with unfavorable prognosis. Vaginal bleeding immediately after removal of the tumor is common. Signs of precocious puberty abate and may disappear within a few months after the operation. The secretion of estrogens returns to normal.

Sex cord tumor with annular tubules is a distinctive tumor, thought to arise from granulosa cells, that occurs primarily in patients with Peutz-Jeghers syndrome. These tumors are multifocal, bilateral, and usually benign. The presence of calcifications aids ultrasonographic detection. Increased aromatase production by these tumors results in gonadotropin-independent precocious puberty. Inhibin A and B levels

are elevated and decrease after tumor removal. In 1 study, 9 of 13 sex cord/stromal tumors exhibited follicle-stimulating hormone receptor mutations, suggesting a role for such mutation in the development of these tumors.

Chorioepithelioma has been reported only rarely. This highly malignant tumor is thought to arise from a preexisting teratoma. The usually unilateral tumor produces large amounts of human chorionic gonadotropin, which stimulates the contralateral ovary to secrete estrogen. Elevated levels of human chorionic gonadotropin are diagnostic.

Follicular Cyst

Small ovarian cysts (<0.7 cm in diameter) are common in prepubertal children. At puberty and in girls with true isosexual precocious puberty, larger cysts (1-6 cm) are often seen; these are secondary to stimulation by gonadotropins. However, similar larger cysts occur occasionally in young girls with precocious puberty in the absence of luteinizing hormone and follicle-stimulating hormone. Because surgical removal or spontaneous involution of these cysts results in regression of pubertal changes, there is little doubt that they are its cause. The mechanism of production of these autonomously functioning cysts is unknown. Such cysts may form only once, or they may disappear and recur, resulting in waxing and waning of the signs of precocious puberty. They may be unilateral or bilateral. The sexual precocity that occurs in young girls with **McCune-Albright syndrome** is usually associated with autonomous follicular cysts caused by a somatic-activating mutation of the $G_S\alpha$-protein occurring early in development (see Chapter 562.6). Gonadotropins are suppressed, and estradiol levels are often markedly elevated, but they may fluctuate widely and even temporarily may return to normal. Gonadotropin-releasing hormone analog stimulation fails to evoke an increase in gonadotropins. Ultrasonography is the method of choice for the detection and monitoring of such cysts. Aromatase inhibitors are shown to be the mainstay of the therapy in females with McCune-Albright syndrome and persistent estradiol elevation. A short period of observation to ascertain the lack of spontaneous resolution is advisable before cyst aspiration or cystectomy is considered. Cystic neoplasms must be considered in the differential diagnosis.

ANDROGENIC LESIONS OF THE OVARY

Virilizing ovarian tumors are rare at all ages but particularly so in prepubertal girls. **Arrhenoblastoma** has been reported as early as 14 days of age, but few cases have been reported in girls younger than 16 yr of age.

The **gonadoblastoma** occurs exclusively in dysgenetic gonads, particularly in phenotypic females who have a Y chromosome or a Y fragment in their genotype (46,XY; 45,X/46,XY; 45,X/46,X-fra). As noted above, there is a proposed gonadoblastoma locus on the Y chromosome (GBY). The tumors may be bilateral. Virilization occurs with some but not all tumors. The clinical features are the same as those seen in patients with virilizing adrenal tumors and include accelerated growth, acne, clitoral enlargement, and growth of sexual hair. A palpable, abdominal mass is found in about 50% of patients. Plasma levels of testosterone and androstenedione are elevated, and gonadotropins are suppressed. Ultrasonography, CT, and MRI usually localize the lesion. The dysgenetic gonad of phenotypic females with a Y chromosome or fragment of Y chromosome containing GBY should be removed prophylactically. When a unilateral tumor is removed, the contralateral dysgenetic gonad should also be removed. Association of gonadoblastoma and WAGR (Wilms, aniridia, genitourinary anomalies, mental retardation) syndrome is also reported in the literature. In an immunohistochemical study of 2 gonadoblastomas, expressions of *WT1, p53,* and *MIS*, as well as inhibin, were all demonstrated.

Virilizing manifestations occur occasionally in girls with **juvenile granulosa cell tumors.** Adrenal rests and hilum cell tumors rarely lead to virilization. Activating mutations of G-protein genes have been described in ovarian (and testicular) tumors. $G_S\alpha$ mutations, usually seen in gonadal tumors associated with **McCune-Albright syndrome,** were also noted in 4 of 6 Leydig cell tumors (3 ovarian, 1 testicular). Two granulosa cell tumors and 1 thecoma of 10 ovarian tumors studied were found to have *GIP-2* mutations.

Sertoli-Leydig cell tumors, rare sex cord/stromal neoplasms, constitute less than 1% of ovarian tumors. The average age at diagnosis is 25 yr; less than 5% of these tumors occur before puberty. α-Fetoprotein levels may be mildly elevated. In one 12 mo old with Sertoli-Leydig cell tumor presenting with isosexual precocity the only detectable tumor marker was the serum inhibin level, with elevations in both A and B subunits. Five-year survival rates are 70-90%.

Of 102 consecutive patients who underwent surgery because of ovarian masses over a 15 yr period, the presenting symptoms were acute abdominal pain in 56% and abdominal or pelvic mass in 22%. Of 9 children whose cause for surgery was presumed malignancy, 3 had dysgerminomas, 2 had teratomas, 2 had juvenile granulosa cell tumors, 1 had a Sertoli-Leydig cell tumor, and 1 had a yolk sac tumor.

Chapter 588

Disorders of Sex Development

Patricia A. Donohoue

SEX DIFFERENTIATION

See also Chapter 582.

In normal differentiation, the final form of all sexual structures is consistent with normal sex chromosomes (either XX or XY). A 46,XX complement of chromosomes as well as genetic factors such as DAX1 (dosage-sensitive/sex-reversal adrenal hypoplasia on the X chromosome), the signaling molecule WNT-4, and R-Spondin1 are among the many needed for the development of normal ovaries. Development of the male phenotype is potentially more complex. It requires a Y chromosome and, specifically, an intact *SRY* (sex-determining region on the Y chromosome) gene, which, in association with other genes such as *SOX9, SF-1* (steroidogenic factor-1), *WT1* (Wilms tumor 1), and others (see Chapter 582), directs the undifferentiated gonad to become a testis. Aberrant recombinations may result in X chromosomes carrying *SRY,* resulting in XX males, or Y chromosomes that have lost *SRY,* resulting in XY females. Epigenetic causes of abnormal sex differentiation have been shown in plants, invertebrates, and vertebrates, and will likely contribute to human disorders of sex development (DSDs) as well.

Antimüllerian hormone (AMH) causes the müllerian ducts to regress; in its absence, they persist as the uterus, fallopian tubes, cervix, and upper vagina. AMH activation in the testes may require the *SF-1* gene. By about 8 wk of gestation, the Leydig cells of the testis begin to produce testosterone. During this critical period of male differentiation, testosterone secretion is stimulated by placental human chorionic gonadotropin (hCG), which peaks at 8-12 wk. In the latter half of pregnancy, lower levels of testosterone are maintained by luteinizing hormone (LH) secreted by the fetal pituitary. Testosterone produced locally initiates development of the ipsilateral wolffian duct into the epididymis, vas deferens, and seminal vesicle. Development of the external genitalia also requires dihydrotestosterone (DHT), the more active metabolite of testosterone. DHT is produced largely from circulating testosterone and is necessary to fuse the genital folds to form the penis and scrotum. DHT is also produced via an alternative biosynthetic pathway from androstanediol, and this pathway must be intact for normal and complete prenatal virilization to occur. A functional androgen receptor, produced by an X-linked gene, is required for testosterone and DHT to induce these androgen effects.

In the XX fetus with normal long and short arms of the X chromosome, the bipotential gonad develops into an ovary by about the 10th-11th wk. This occurs only in the absence of SRY, testosterone, and AMH and requires a normal gene in the dosage-sensitive/sex-reversal

Table 588-1 Revised Nomenclature

PREVIOUS	CURRENTLY ACCEPTED
Intersex	Disorders of sex development (DSD)
Male pseudohermaphrodite	46,XY DSD
Undervirilization of an XY male	46,XY DSD
Undermasculinization of an XY male	46,XY DSD
46,XY intersex	46,XY DSD

locus DAX1, the WNT-4 molecule, and R-Spondin1. A female external phenotype develops in the absence of fetal gonads. However, the male phenotype development requires androgen production and action. Estrogen is unnecessary for normal prenatal sexual differentiation, as demonstrated by 46,XX patients with aromatase deficiency and by mice without estradiol receptors.

Chromosomal aberrations may result in ambiguity of the external genitalia. Conditions of aberrant sex differentiation may also occur with the XX or XY genotype. The appropriate term for what was previously called *intersex* is **DSD.** This term defines a condition "in which development of chromosomal, gonadal, or anatomical sex is atypical." It is increasingly preferable to use the term "atypical genitalia" rather than "ambiguous genitalia." Tables 588-1 and 588-2 compare previous terms with their revised etiologic classification nomenclature. Table 582-1 in Chapter 582 lists some of the genes that are mutated in various forms of DSD.

The definition of atypical or ambiguous genitalia, in a broad sense, is any case in which the external genitalia do not appear completely male or completely female. Although there are standards for genital size dimensions, variations in size of these structures do not always constitute ambiguity.

Development of the external genitalia begins with the potential to be either male or female (Fig. 588-1). Virilization of a female, the most common form of DSD, results in varying phenotypes (Fig. 588-2), that develop from the basic bipotential genital appearances of the embryo (Fig. 588-1).

DIAGNOSTIC APPROACH TO THE PATIENT WITH ATYPICAL OR AMBIGUOUS GENITALIA

The appearance of the external genitalia is rarely diagnostic of a particular disorder, and thus does not often allow distinction among the various forms of DSD. The most common forms of 46,XX DSD are virilizing forms of congenital adrenal hyperplasia. It is important to note that in 46,XY DSD, the specific diagnosis is not found in up to 50% of cases; partial androgen insensitivity syndrome and pure gonadal dysgenesis are common identifiable etiologies in XY DSD. At 1 center with a large experience, the etiologies of DSD in 250 patients over 25 yr were compiled. The 6 most common diagnoses accounted for 50% of the cases. These included virilizing congenital adrenal hyperplasia (14%), androgen insensitivity syndrome (10%), mixed gonadal dysgenesis (8%), clitoral/labial anomalies (7%), hypogonadotropic hypogonadism (6%), and 46,XY small-for-gestational-age males with hypospadias (6%).

Table 588-2 Etiologic Classification of Disorders of Sex Development (DSD)

46,XX DSD
Androgen Exposure
Fetal/Fetoplacental Source
21-Hydroxylase (P450c21 or CYP21) deficiency
11β-Hydroxylase (P450c11 or CYP11B1) deficiency
3β-Hydroxysteroid dehydrogenase II (3β-HSD II) deficiency
Cytochrome P450 oxidoreductase (POR)
Aromatase (P450arom or CYP19) deficiency
Glucocorticoid receptor gene mutation
Maternal Source
Virilizing ovarian tumor
Virilizing adrenal tumor
Androgenic drugs
Disorder of Ovarian Development
XX gonadal dysgenesis
Testicular DSD (SRY+, SOX9 duplication)
Undetermined Origin
Associated with genitourinary and gastrointestinal tract defects

46,XY DSD
Defects in Testicular Development
Denys-Drash syndrome (mutation in *WT1* gene)
WAGR syndrome (Wilms tumor, aniridia, genitourinary malformation, retardation)
Deletion of 11p13
Campomelic syndrome (autosomal gene at 17q24.3-q25.1) and *SOX9* mutation
XY pure gonadal dysgenesis (Swyer syndrome)
Mutation in *SRY* gene
XY gonadal agenesis
Unknown cause
Deficiency of Testicular Hormones
Leydig cell aplasia
Mutation in LH receptor
Lipoid adrenal hyperplasia (P450scc or CYP11A1) deficiency; mutation in StAR (steroidogenic acute regulatory protein)
3β-HSD II deficiency
17-Hydroxylase/17,20-lyase (P450c17 or CYP17) deficiency
Persistent müllerian duct syndrome because of antimüllerian hormone gene mutations or receptor defects for antimüllerian hormone
Defect in Androgen Action
Dihydrotestosterone deficiency because of 5α-reductase II mutations or *AKR1C2/AKR1C4* mutations
Androgen receptor defects:
Complete androgen insensitivity syndrome
Partial androgen insensitivity syndrome
(Reifenstein and other syndromes)
Smith-Lemli-Opitz syndrome (defect in conversion of 7-dehydrocholesterol to cholesterol, DHCR7)
Ovotesticular DSD
XX
XY
XX/XY chimeras
Sex Chromosome DSD
45,X (Turner syndrome and variants)
47,XXY (Klinefelter syndrome and variants)
45,X/46,XY (mixed gonadal dysgenesis, sometimes a cause of ovotesticular DSD)
46,XX/46,XY (chimeric, sometimes a cause of ovotesticular DSD)

From Lee PA, Houk CP, Ahmed SF, et al: Consensus statement on management of intersex disorders, Pediatrics *118:e488–e500, 2006.*

The relative lack of established diagnoses in 46,XY DSD and the resulting lack of specific management emphasizes the need for thorough diagnostic evaluations. These include biochemical characterization of possible steroidogenic enzymatic defects in each patient with genital ambiguity. The parents need counseling about the potentially complex nature of the baby's condition, and guidance as to how to deal with their well-meaning but curious friends and family members. The

evaluation and management should be carried out by a multidisciplinary team of experts that includes pediatric endocrinology, pediatric surgery/urology, pediatric radiology, newborn medicine, genetics, and psychology. Once the sex of rearing has been agreed on by the family and team, treatment can be organized. Genetic counseling should be offered when the specific diagnosis is established.

After a complete history and physical exam, the common diagnostic approach includes multiple steps, described in the following outline. These steps are usually performed simultaneously rather than waiting for results of 1 test prior to performing another, because of the sensitive and sometimes urgent nature of the condition. Careful attention to the presence of physical features other than the genitalia is crucial, to determine if a diagnosis of a particular multisystem syndrome is possible. These are described in more detail in Chapters 588.1, 588.2, and 588.3 below. Table 588-3 summarizes many of the features of commonly encountered causes of DSD.

Diagnostic tests include the following:

1. Karyotype, with rapid determination of sex chromosomes (in many centers this is available within 24-48 hr)
2. Other blood tests
   a. Screen for congenital adrenal hyperplasia: cortisol biosynthetic precursors and adrenal androgens (particularly 17-hydroxyprogesterone and androstenedione for 21-hydroxylase deficiency, the most common form)
   b. Screen for androgens and their biosynthetic precursors
   c. Screen for gonadal response to gonadotropin in patients suspected of having testicular gonads: stimulation with injections of hCG; measure testosterone and DHT before and after hCG
   d. Molecular genetic analyses for SRY and other Y-specific loci
   e. Gonadotropin levels
3. The internal anatomy of patients with ambiguous genitalia can be defined with 1 or more of the following studies:
   a. Voiding cystourethrogram
   b. Endoscopic examination of the genitourinary tract
   c. Pelvic ultrasound; renal and adrenal ultrasound
   d. Pelvic CT or MRI
   e. Exploratory laparoscopy

588.1 46,XX DSD

Patricia A. Donohoue

In this condition, the genotype is XX and the gonads are ovaries but the external genitalia are virilized. There is no significant AMH production because the gonads are ovaries. Thus the uterus, fallopian tubes, and cervix develop. The varieties and causes of this condition are relatively few. Most instances result from exposure of the female fetus to excessive exogenous or endogenous androgens during intrauterine life. The changes consist principally of virilization of the external genitalia (clitoral hypertrophy and labioscrotal fusion).

CONGENITAL ADRENAL HYPERPLASIA

See Chapter 576.1.

This is the most common cause of genital ambiguity and of 46,XX DSD. Females with the 21-hydroxylase and 11-hydroxylase defects are the most highly virilized, although minimal virilization also occurs with the type II 3β-hydroxysteroid dehydrogenase defect (see Fig. 588-1). Female patients with salt-losing congenital adrenal hyperplasia tend to have more virilization than do non–salt-losing patients. Masculinization may be so intense that a complete penile urethra results, and the patient may appear to be a male with bilateral cryptorchidism.

AROMATASE DEFICIENCY

In genotypic females, the rare condition of aromatase deficiency during fetal life leads to 46,XX DSD and results in hypergonadotropic hypogonadism at puberty because of ovarian failure to synthesize estrogen.

Two 46,XX infants had enlargement of the clitoris and posterior labial fusion at birth. In 1 instance, maternal serum and urinary levels of estrogen were very low and serum levels of androgens were high. Cord serum levels of estrogen were also extremely low, but those of androgen were elevated. The second patient also had virilization of unknown cause since birth, but the aromatase deficiency was not diagnosed until 14 yr of age, when she had further virilization and failed to go into puberty. At that time, she had elevated levels of gonadotropins and androgens but low estrogen levels, and ultrasonography

revealed large ovarian cysts bilaterally. These 2 patients demonstrate the important role of aromatase in the conversion of androgens to estrogens. Additional female and male patients with aromatase deficiency as a consequence of mutations in the *aromatase gene (CYP19)* are known. Two siblings were described. The 28 yr old XX proband was 177.6 cm tall (+2.5 SD) after having received hormonal replacement therapy; her 24 yr old brother was 204 cm tall (+3.7 SD), and had a bone age of 14 yr. Low-dose estradiol replacement, carefully adjusted to maintain normal age-appropriate levels, may be indicated for affected females, even prepubertally.

GLUCOCORTICOID RECEPTOR GENE MUTATION

A 9 yr old girl with 46,XX disorder of sexual development, thought to be caused by 21-hydroxylase deficiency (congenital adrenal hyperplasia) since the age of 5 yr, had elevated cortisol levels both at baseline and after dexamethasone, hypertension, and hypokalemia, suggestive of the diagnosis of generalized glucocorticoid resistance. A novel homozygous mutation in exon 5 of the glucocorticoid receptor was demonstrated. In this Brazilian family, the condition was autosomal recessive.

Cytochrome P450 oxidoreductase, encoded by a gene on 7q11.2, is a cofactor implicated in combined P450C17 and P450C21 steroidogenic defects. Girls are born with ambiguous genitalia, but the virilization does not progress postnatally and androgen levels are normal or low. Boys may be born undervirilized. Both may exhibit bony abnormalities seen in **Antley-Bixler syndrome**. Conversely, in a series of Antley-Bixler syndrome patients, those with ambiguous genitalia and disordered steroidogenesis had cytochrome P450 oxidoreductase deficiency. Those without genital ambiguity with normal steroidogenesis had fibroblast growth factor receptor 2 (*FGFR2)* mutations. The cardinal features of Antley-Bixler syndrome include craniosynostosis, severe midface hypoplasia, proptosis, choanal atresia/stenosis, frontal bossing, dysplastic ears, depressed nasal bridge, radiohumeral synostosis, long bone fractures and femoral bowing, and urogenital abnormalities.

VIRILIZING MATERNAL TUMORS

Rarely, the female fetus has been virilized during fetal life by a maternal androgen-producing tumor. In a few cases, the lesion was a benign adrenal adenoma, but all others were ovarian tumors, particularly androblastomas, luteomas, and Krukenberg tumors (Table 588-4). **Maternal virilization** may be manifested by enlargement of the clitoris, acne, deepening of the voice, decreased lactation, hirsutism, and elevated levels of androgens. In the infant, there is enlargement of the clitoris of varying degrees, often with labial fusion. Mothers of children with unexplained 46,XX DSD should undergo physical examination and measurements of their own levels of plasma testosterone, dehydroepiandrosterone sulfate, and androstenedione.

Table 588-4 Sources of Maternal-Derived Androgens

ADMINISTRATION OF ANDROGENIC DRUGS TO WOMEN DURING PREGNANCY

Testosterone and 17-methyltestosterone have been reported to cause 46,XX DSD in some instances (see Table 588-4). The greatest number of cases has resulted from the use of certain progestational compounds for the treatment of threatened abortion. These progestins have been replaced by nonvirilizing ones.

Infants with virilization and 46,XX chromosomes and caudal anomalies have been reported for whom no virilizing agent could be identified. In such instances, the disorder is usually associated with other congenital defects, particularly of the urinary and gastrointestinal tracts. Y-specific DNA sequences, including SRY, are absent. In 1 case, a scrotal raphe and elevated testosterone levels were found, but the cause remains unknown.

Bibliography is available at Expert Consult.

588.2 46,XY DSD

Patricia A. Donohoue

In this condition, the genotype is XY but the external genitalia are either not completely virilized, are ambiguous (atypical), or are completely female. When gonads can be found, they invariably contain testicular elements; their development ranges from rudimentary to normal. Because the process of normal virilization in the fetus is so complex, it is not surprising that there are many varieties and causes of 46,XY DSD. As noted earlier, the etiology of 46,XY DSD is not identified in approximately 50% of cases.

DEFECTS IN TESTICULAR DIFFERENTIATION

The first step in male differentiation is conversion of the bipotential gonad into a testis. In the XY fetus, if there is a deletion of the short arm of the Y chromosome or of the *SRY* gene, male differentiation does not occur. The phenotype is female; müllerian ducts are well developed because of the absence of AMH, and gonads consist of undifferentiated streaks. By contrast, even extreme deletions of the long arm of the Y chromosome (Yq−) have been found in normally developed males, most of whom are azoospermic and have short stature. This indicates that the long arm of the Y chromosome normally has genes that prevent these manifestations. In many syndromes in which the testes fail to differentiate, Y chromosomes are morphologically normal.

Denys-Drash Syndrome

The constellation of nephropathy with ambiguous genitalia and **bilateral Wilms tumor** is the major phenotype of this syndrome. Most reported cases have been 46,XY. Müllerian ducts are often present, indicating a global deficiency of fetal testicular function. Patients with a 46,XX karyotype have normal external genitalia. The onset of proteinuria in infancy progresses to **nephrotic syndrome** and end-stage renal failure by 3 yr of age, with focal or diffuse mesangial sclerosis being the most consistent histopathologic finding. Wilms tumor usually develops in children younger than 2 yr of age and is frequently bilateral. Gonadoblastomas have also been reported.

Several mutations of the *WT1* gene, located on chromosome 11p13, have been found. *WT1* functions as a tumor-suppressor gene and a transcriptional factor, and is expressed in the genital ridge and fetal gonads. Nearly all reported mutations have been near or within the zinc finger–coding region. One report found a zinc finger domain mutation in the *WT1* alleles of a patient with no genitourinary abnormalities, suggesting that some cases of sporadic Wilms tumor may carry the *WT1* mutation. Different mutations of the *WT1* gene, con-

stitutional heterozygote mutations at intron 9, have been described in **Fraser syndrome,** a condition of nonspecific focal and segmental glomerulosclerosis, 46,XY gonadal dysgenesis, and frequent gonadoblastoma, but **without** Wilms tumor.

WAGR Syndrome

This acronymic contiguous gene syndrome consists of Wilms tumor, aniridia, genitourinary malformations, and retardation (WAGR). These children have a deletion of 1 copy of chromosome 11p13, which may be visible on karyotype analysis. The deleted region encompasses the aniridia gene *(PAX6)* and the Wilms tumor-suppressor gene *(WT1).* Only the 46,XY males have genital abnormalities, ranging from cryptorchidism to severe deficiency of virilization. Gonadoblastomas have developed in the dysgenetic gonads. Wilms tumor usually occurs by 2 yr of age. Some cases also had unexplained obesity, raising the question of an obesity-associated gene in this region of chromosome 11 and naming the syndrome **WAGRO.**

Campomelic Syndrome

See Chapter 704.

This form of **short-limbed dysplasia** is characterized by anterior bowing of the femur and tibia, small, bladeless scapulae, small thoracic cavities, and 11 pairs of ribs, along with malformations of other organs. It is usually lethal in early infancy. Approximately 75% of reported 46,XY patients exhibit a completely **female phenotype;** the external and internal genitalia are female. Some 46,XY patients have ambiguous genitals. The gonads appear to be ovaries but histologically may contain elements of both ovaries and testes.

The gene responsible for the condition is *SOX9* (SRY-related HMG [high-mobility group]-box gene) and is on 17q24-q25. This gene is structurally related to *SRY* and also directly regulates development of the type II collagen gene *(COL2A1).* The same mutations may result in different gonadal phenotypes. Gonadoblastoma was reported in a patient with this condition. The inheritance is autosomal dominant. Adrenal insufficiency and 46,XY gonadal dysgenesis has been described in patients with mutations of the *SF-1* gene. In some of these patients, if the mother shares the *SF-1* mutation, she has premature ovarian insufficiency.

46,XY sex reversal has been described in patients with deletions of parts of autosomal loci on chromosomes 2q, 9p, and 10q.

XY Pure Gonadal Dysgenesis (Swyer Syndrome)

The designation "pure" distinguishes this condition from forms of gonadal dysgenesis that are of chromosomal origin and associated with somatic anomalies. Affected patients have normal stature and a **female phenotype,** including vagina, uterus, and fallopian tubes, but at pubertal age, breast development and menarche fail to occur. None of the other phenotypic features associated with 45,X are present. Patients present at puberty with hypergonadotropic primary amenorrhea. Familial cases suggest an X-linked or a sex-limited dominant autosomal transmission. Most of the patients examined have had mutations of the *SRY* gene. None had a *SOX9* gene mutation. The gonads consist of almost totally undifferentiated streaks despite the presence of a cytogenetically normal Y chromosome. The primitive gonad cannot accomplish any testicular function, including suppression of müllerian ducts. There may be hilar cells in the gonad capable of producing some androgens; accordingly, some virilization, such as clitoral enlargement, may occur at the age of puberty. The streak gonads may undergo neoplastic changes, such as gonadoblastomas and dysgerminomas, and should be removed as soon as the diagnosis is established, regardless of the age of the patient.

Pure gonadal dysgenesis also occurs in XX individuals (see Chapter 586).

XY Gonadal Agenesis Syndrome (Embryonic Testicular Regression Syndrome)

In this rare syndrome, the external genitalia are slightly ambiguous but more nearly **female.** Hypoplasia of the labia; some degree of labioscrotal fusion; a small, clitoris-like phallus; and a perineal urethral opening are present. No uterus, no gonadal tissue, and usually no vagina can be found. At the age of puberty, no sexual development occurs and gonadotropin levels are elevated. Most children have been reared as females. In several patients with XY gonadal agenesis in whom no gonads could be found on exploration, significant rises in testosterone followed stimulation with hCG, indicating Leydig cell function somewhere. Siblings with the disorder are known.

It is presumed that testicular tissue was active long enough during fetal life for AMH to inhibit development of müllerian ducts but not long enough for testosterone production to result in virilization. In 1 patient, no deletion of the Y chromosome was found by means of Y-specific DNA probes. Testicular degeneration seems to occur between the 8th and the 12th fetal wk. Regression of the testis before the 8th wk of gestation results in Swyer syndrome; between the 14th and the 20th wk of gestation, it results in the rudimentary testis syndrome; and after the 20th wk, it results in anorchia.

In **bilateral anorchia,** sometimes referred to as *vanishing testes syndrome*, testes are absent, but the **male phenotype** is complete; it is presumed that tissue with fetal testicular function was active during the critical period of genital differentiation but that sometime later it was damaged. Bilateral anorchia in identical twins and unilateral anorchia in identical twins and in siblings suggest a genetic predisposition. Coexistence of anorchia and the gonadal agenesis syndrome in a sibship is evidence for a relationship between the disorders. *SRY* defects have not yet been reported for patients with anorchia.

A retrospective review of urologic explorations revealed absent testes in 21% of 691 testes. Of those, 73% had blind-ending cord structures with the suggested site of the vanishing testes being the inguinal canal (59%), abdomen (21%), superficial inguinal ring (18%), and scrotum (2%). It was suggested that the presence of cord structures on laparoscopy should prompt inguinal exploration because viable testicular tissue was found in 4 of these children. No hormonal data (hCG stimulation tests, AMH levels) were reported.

DEFECTS IN TESTICULAR HORMONES

Five genetic defects have been delineated in the enzymatic synthesis of testosterone by the fetal testis, and a defect in Leydig cell differentiation has been described. These defects produce 46,XY males with inadequate masculinization (see Fig. 582-1 in Chapter 582). Because levels of testosterone are normally low before puberty, an hCG stimulation test may be needed in children to assess the ability of the testes to synthesize testosterone.

Leydig Cell Aplasia

Patients with aplasia or hypoplasia of the Leydig cells usually have **female phenotypes,** but there may be mild virilization. Testes, epididymis, and vas deferens are present; the uterus and fallopian tubes are absent because of normal production of AMH. There are no secondary sexual changes at puberty, but pubic hair may be normal. Plasma levels of testosterone are low and do not respond to hCG; LH levels are elevated. The Leydig cells of the testes are absent or markedly deficient. The defect may involve a lack of receptors for LH. In children, hCG stimulation is necessary to differentiate the condition from the androgen insensitivity syndromes (AISs). There is male-limited autosomal recessive inheritance. The human LH receptor is a member of the G-protein–coupled superfamily of receptors that contains 7 transmembrane domains. Several inactivating mutations of the LH receptor have been described in males with hypogonadism suspected of having Leydig cell hypoplasia or aplasia.

High serum LH and low follicle-stimulating hormone were noted in 1 male with hypogonadism owing to a mutation in the gene for the β-subunit of follicle-stimulating hormone (see Table 583-1 in Chapter 583).

Lipoid Adrenal Hyperplasia

See Chapter 576.

The most severe form of congenital adrenal hyperplasia derives its name from the appearance of the enlarged adrenal glands resulting from accumulation of cholesterol and cholesterol esters. The rate-limiting process in steroidogenesis is the transport of free cholesterol

through the cytosol to the inner mitochondrial membrane, where the P450 side-chain cleavage enzyme (P450scc; CYP11A1) acts. Cholesterol transport into mitochondria is mediated by the steroidogenetic acute regulatory protein (StAR) whose synthesis occurs via cyclic adenosine monophosphate through a cyclic adenosine monophosphate response element–binding protein. StAR is a 30 kDa protein essential for steroidogenesis and is encoded by a gene on chromosome 8p11.2. The mitochondrial content of StAR increases between 1 and 5 hr after adrenocorticotropic hormone stimulation, long after the acute adrenocorticotropic hormone–induced increase in steroidogenesis. This has led some to suggest that extramitochondrial StAR might also be involved in the acute response to adrenocorticotropic hormone.

All serum steroid levels are low or undetectable, whereas corticotropin and plasma renin levels are quite elevated. The phenotype is female in both genetic females and males. Genetic males have no müllerian structures because the testes can produce normal AMH but no steroid hormones. These children present with acute adrenal crisis and salt wasting in infancy. Most patients are 46,XY. In a few patients, ovarian steroidogenesis is present at puberty.

The regulatory role of StAR-independent steroidogenesis is illustrated by 46,XX 4 mo old twins with lipoid adrenal hyperplasia. One died at 15 mo because of cardiac complications related to coarctation of the aorta. The adrenal glands had characteristic lipid deposits. The surviving twin had spontaneous puberty with feminization at 11.5 yr and menarche at 13.8 yr. When restudied at the age of 15 yr, a homozygous frameshift-inactivating mutation in her *StAR* gene was discovered. This and the fact that she survived as an infant until 4 mo of age without replacement therapy with detectable serum aldosterone levels supports the hypothesis that StAR-independent steroidogenesis was able to proceed until enough intracellular lipid accumulated to destroy steroidogenic activity. Partial defects in only partially virilized males and delayed onset of salt wasting have been described. Complete P450scc defects may be incompatible with life because only this enzyme can convert cholesterol to pregnenolone, which then becomes progesterone, a hormone essential for the maintenance of normal mammalian pregnancy. Heterozygous mutation in *CYP11A1* was described in a 4 yr old with 46,XY sex reversal and late-onset form of lipoid adrenal hyperplasia. At 6-7 wk of gestation, when maternal corpus luteum progesterone synthesis stops, the placenta, which does not express StAR, produces progesterone by StAR-independent steroidogenesis using the CYP11A1 enzyme system.

3β-Hydroxysteroid Dehydrogenase Deficiency

Males with this form of congenital adrenal hyperplasia (see Chapter 576) have various degrees of **hypospadias,** with or without bifid scrotum and cryptorchidism and, rarely, a complete female phenotype. Affected infants usually develop salt-losing manifestations shortly after birth. Incomplete defects, occasionally seen in boys with premature pubarche, as well as late-onset nonclassic forms, have been reported. These children have point mutations of the gene for type II 3β-hydroxysteroid enzyme, resulting in impairment of steroidogenesis in the adrenals and gonads; the impairment may be unequal between adrenals and gonads. Normal pubertal changes in some boys could be explained by the normally present type I 3β-hydroxysteroid dehydrogenase present in many peripheral tissues. Infertility is frequent. There is no correlation between degree of salt wasting and degree of phenotypic abnormality.

Deficiency of 17-Hydroxylase/17,20-Lyase

A single enzyme (CYP17A1) encoded by a single gene on chromosome 10q24.3 has both 17-hydroxylase and 17,20-lyase activities in adrenal and gonadal tissues (see Chapter 576). Many different genetic lesions have been reported. Genetic males usually have a complete female phenotype or, less often, various degrees of undervirilization from labioscrotal fusion to perineal hypospadias and cryptorchidism. Pubertal development fails to occur in both genetic sexes.

In the classical disorder, there is decreased synthesis of cortisol by the adrenals and of sex steroids by the adrenals and gonads. Levels of deoxycorticosterone and corticosterone are markedly increased and lead to the hypertension and hypokalemia characteristic of this form of male DSD. Although levels of cortisol are low, the elevated corticotropin and corticosterone levels prevent symptomatic cortisol deficiency. The renin–aldosterone axis is suppressed because of the strong mineralocorticoid effect of elevated deoxycorticosterone. Virilization does not occur at puberty; levels of testosterone are low, and those of gonadotropins are increased. Because fetal production of AMH is normal, no müllerian duct remnants are present. In phenotypic XY females, gonadectomy and replacement therapy with hydrocortisone and sex steroids are indicated.

The defect follows autosomal recessive inheritance. Affected XX females are usually not detected until young adult life, when they fail to experience normal pubertal changes and are found to have hypertension and hypokalemia. This condition should be suspected in patients presenting with primary amenorrhea and hypertension whose chromosomal complement is either 46,XX or 46,XY.

Deficiency of 17-Ketosteroid Reductase

This enzyme, also called *17β-hydroxysteroid dehydrogenase*, catalyzes the final step in testosterone biosynthesis. It is necessary to convert androstenedione to testosterone and also dehydroepiandrosterone to androstenediol and estrone to estradiol. Enzymatic defects in the fetal testis give rise to males with complete or near-complete female phenotype in 46,XY males. Müllerian ducts are absent, and a shallow vagina is present. The diagnosis is based on the ratio of androstenedione to testosterone; in prepubertal children, stimulation with hCG may be necessary to make the diagnosis.

The defect is inherited in an autosomal recessive fashion. At least 4 different types of 17β-hydroxysteroid dehydrogenase are recognized, each coded by a different gene or different chromosomes. Type III is the enzyme defect that is especially common in a highly inbred Arab population in Gaza. The gene for the disorder is at 9q22 and is expressed only in the testes, where it converts androstenedione to testosterone. Most patients are diagnosed at puberty because of virilization and the failure to menstruate. Testosterone levels at puberty may approach normal, presumably as a result of peripheral conversion of androstenedione to testosterone; at this time, some patients spontaneously adopt a male gender role.

Type I 17β-hydroxysteroid dehydrogenase, encoded by a gene on chromosome 17q21, converts estrone to estradiol and is found in placenta, ovary, testis, liver, prostate, adipose tissue, and endometrium. Type II, whose gene is on chromosome 16q24, reverses the reactions of types I and III (converting testosterone to androstenedione and estrone to estradiol, respectively). Type IV is similar in action to type II. A late-onset form of 17-ketosteroid reductase deficiency presents as gynecomastia in young adult males.

Persistent Müllerian Duct Syndrome

In this disorder, there is persistence of müllerian duct derivatives in otherwise completely virilized males. Cases have been reported in siblings and identical twins. **Cryptorchidism** is present in 80% of affected males; and during surgery for this or inguinal hernia, the condition is uncovered when a fallopian tube and uterus are found. The degree of müllerian development is variable and may be asymmetric. Testicular function is normal in most, but testicular degeneration has been reported. Some affected males acquire testicular tumors after puberty. In a study of 38 families, 16 families had defects in the AMH gene, located on the short arm of chromosome 19. They had low AMH levels. In 16 families with high AMH levels, the defect was in the AMH type II receptor gene, with 10 of 16 having identical 27-bp deletions on exon 10 in at least 1 allele.

Treatment consists of removal of as many of the müllerian structures as possible without causing damage to the testis, epididymis, or vas deferens.

DEFECTS IN ANDROGEN ACTION

In the following group of disorders, fetal synthesis of testosterone is normal and defective virilization results from inherited abnormalities in androgen action.

Dihydrotestosterone Deficiency

Decreased production of DHT in utero results in marked ambiguity of external genitalia of affected males. Biosynthesis and peripheral action of testosterone are normal.

The phenotype most commonly associated with this condition results in boys who have a small phallus, bifid scrotum, urogenital sinus with perineal hypospadias, and a blind vaginal pouch (Fig. 588-3). Testes are in the inguinal canals or labioscrotal folds and are normal histologically. There are no müllerian structures. Wolffian structures—the vas deferens, epididymis, and seminal vesicles—are present. Most affected patients have been identified as females. At puberty, virilization occurs; the phallus enlarges, the testes descend and grow normally, and spermatogenesis occurs. There is no gynecomastia. Beard growth is scanty, acne is absent, the prostate is small, and recession of the temporal hairline fails to occur. Virilization of the wolffian duct is caused by the action of testosterone itself, although masculinization of the urogenital sinus and external genitals depends on the action of DHT during the critical period of fetal masculinization. Growth of facial hair and of the prostate also appears to be DHT dependent.

The adult height reached is close to that of the father and other male siblings. There is significant phenotypic heterogeneity. This has led to a classification of such patients into 5 types of steroid 5α-reductase deficiency (SRD).

Several different gene defects of SRD5A2 (the 5α-reductase type 2 gene leading to SRD) have been identified, located on the short arm of chromosome 2, in patients from throughout the world. Familial clusters have been reported from the Dominican Republic, Turkey, Papua New Guinea, Brazil, Mexico, and the Middle East. There is no reliable correlation between genotype and phenotype.

The disorder is inherited as an autosomal recessive trait but is limited to males; normal homozygous females with normal fertility indicate that in females DHT has no role in sexual differentiation or in ovarian function later in life. The clinical diagnosis should be made as early as possible in infancy. It is important to distinguish this from partial androgen insensitivity syndrome (PAIS), as patients with PAIS are far less sensitive to androgen than are patients with SRD. The biochemical diagnosis of SRD is based on finding normal serum testosterone levels, normal or low DHT levels with markedly increased basal and especially hCG-stimulated testosterone: DHT ratios (>17), and high ratios of urinary etiocholanolone to androsterone. Children with androgen insensitivity have normal hepatic 5α reduction and, thus, a normal ratio of tetrahydrocortisol to 5α-tetrahydrocortisol, as opposed to those with SRD.

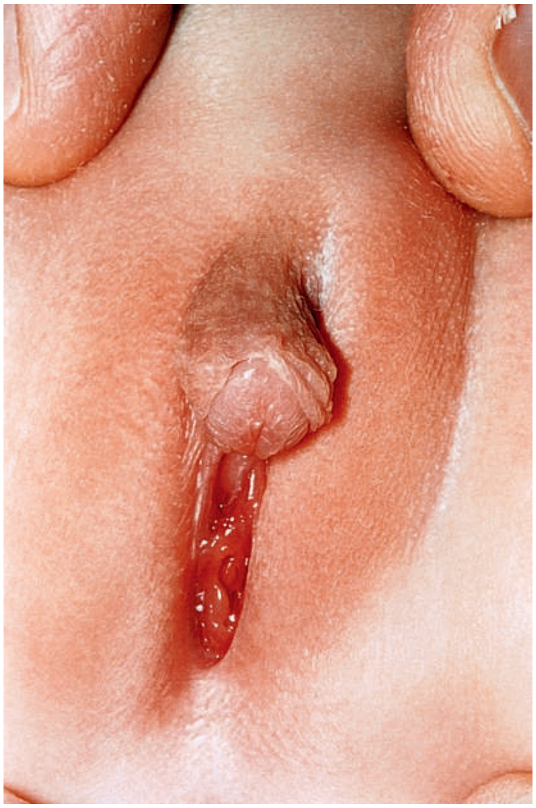

Figure 588-3 5α-Reductase deficiency. *(From Wales JKH, Wit JM, Rogol AD:* Pediatric endocrinology and growth, *ed 2, Philadelphia, 2003, WB Saunders, p. 165.)*

It is important to note that most but not all children with SRD reared as females in childhood have changed to male around the time of puberty. It appears that exposures to testosterone in utero, neonatally, and at puberty have variable contributions to the formation of male gender identity. Much more needs to be learned about the influences of hormones such as androgens as well as the influences of cultural, social, psychologic, genetic, and other biologic factors in gender identity and behavior. Infants with this condition should be reared as boys whenever practical. Treatment of male infants with DHT results in phallic enlargement.

Another cause of DHT deficiency is a block in an alternative pathway of DHT synthesis. Patients previously thought to have 46,XY DSD because of isolated 17,20-lyase deficiency have subsequently been characterized as having mutations in the *AKR1C2* gene (3α-reductase type 3) or both the *AKR1C2* and *AKR1C4* (3α-reductase type 4) genes. These findings showed that both the classical and alternative pathways to DHT must be intact for normal prenatal virilization.

Androgen Insensitivity Syndromes

The AISs are the most common forms of male DSD, occurring with an estimated frequency of 1/20,000 genetic males. This group of heterogeneous X-linked recessive disorders is caused by more than 150 different mutations in the androgen receptor gene, located on Xq11-12: single point mutations resulting in amino acid substitutions or premature stop codons, frameshift and premature terminations, gene deletions, and splice-site mutations.

Clinical Manifestations

The clinical spectrum of patients with AISs, all of whom have a 46,XY chromosomal complement, range from phenotypic females (in complete AIS) to males with various forms of ambiguous genitalia and undervirilization (partial AIS, or clinical syndromes such as **Reifenstein syndrome**) to phenotypically normal-appearing males with infertility. In addition to normal 46,XY chromosomes, the presence of testes and normal or elevated testosterone and LH levels are common to all such children (Figs. 588-4 and 588-5).

In **complete androgen insensitivity syndrome (CAIS),** an extreme form of failure of virilization, genetic males appear female at birth and are invariably reared accordingly. The external genitalia are female. The vagina ends blindly in a pouch, and the uterus is absent as a result of the normal production and effect of AMH by the testes. In about one third of patients, unilateral or bilateral fallopian tube remnants are found. The testes are usually intraabdominal but may descend into the inguinal canal; they consist largely of seminiferous tubules. At puberty, there is normal development of breasts and the habitus is female, but menstruation does not occur and sexual hair is absent. Adult heights of these women are commensurate with those of normal males despite profound congenital deficiency of androgenic effects.

The testes of affected adult patients produce normal male levels of testosterone, which are converted to normal levels of DHT. Failure of normal male differentiation during fetal life reflects a defective response to androgens at that time. The absence of androgenic effects is caused by a striking resistance to the action of endogenous or exogenous testosterone at the cellular level.

Prepubertal girls with this disorder are often detected when inguinal masses prove to be testes or when a testis is unexpectedly found during herniorrhaphy. Approximately 1-2% of girls with an inguinal hernia prove to have this disorder. In infants, elevated LH levels should suggest the diagnosis. In older girls and adults, **amenorrhea** is the usual presenting symptom. In prepubertal children, the condition must

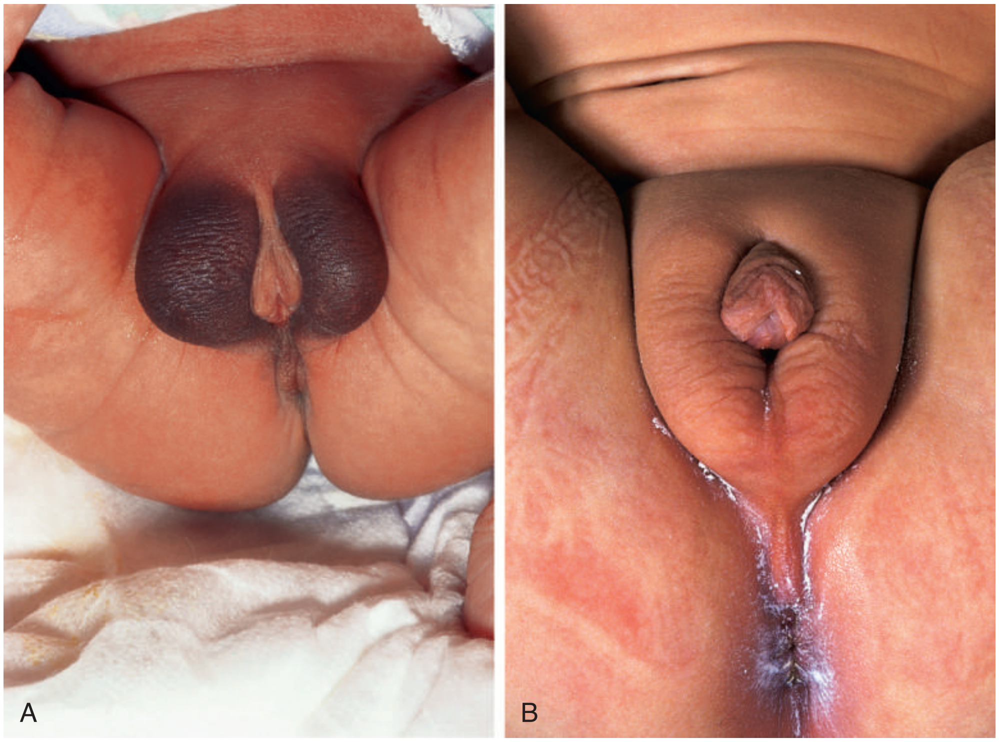

Figure 588-4 **A,** Partial androgen insensitivity with descended testes in bifid labioscrotal folds. **B,** Less-severe partial androgen insensitivity with severe hypospadias and maldescent of testes. *(From Wales JKH, Wit JM, Rogol AD:* Pediatric endocrinology and growth*, ed 2, Philadelphia, 2003, WB Saunders, p. 165.)*

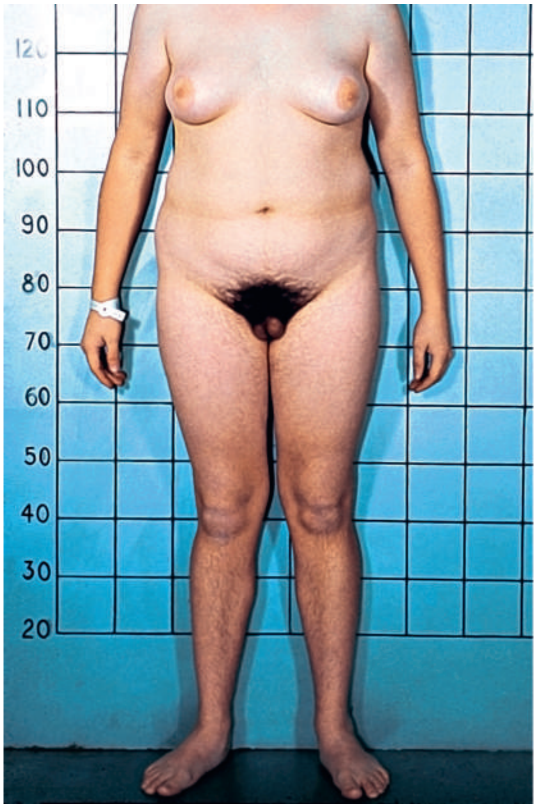

Figure 588-5 **Partial androgen insensitivity syndrome at adolescence, male sex of rearing.** Note gynecomastia from peripheral aromatase conversion of testosterone to estrogen. Abundant pubic hair implies only partial resistance. *(From Wales JKH, Wit JM, Rogol AD:* Pediatric endocrinology and growth*, ed 2, Philadelphia, 2003, WB Saunders, p. 165.)*

be differentiated from other types of XY undervirilized males in which there is complete feminization. These include XY gonadal dysgenesis (Swyer syndrome), true agonadism, Leydig cell aplasia including LH receptor defects, and 17-ketosteroid reductase deficiency; all these conditions, unlike CAIS, are characterized by **low levels of testosterone** as neonates and during adult life and by failure to respond to hCG during the prepubertal years.

Although patients with CAIS have unambiguously female external genitals at birth, those with **PAIS** have a wide variety of phenotypic presentations, ranging from **perineoscrotal hypospadias,** bifid scrotum, and cryptorchidism to extreme undervirilization appearing as clitoromegaly and labial fusion. Some forms of PAIS are known as specific syndromes. Patients with **Reifenstein syndrome** have incomplete virilization characterized by hypogonadism, severe hypospadias, and gynecomastia (see Fig. 588-5). **Gilbert-Dreyfus** and **Lubs** syndromes are also classified as PAISs. In all cases, abnormalities in the androgen receptor gene have been identified. Table 588-5 lists other causes of a PAIS-like syndrome.

Diagnosis

The diagnosis of patients with PAIS may be particularly difficult in infancy. The postnatal surge in testosterone and LH is diminished in those with CAIS but not in those with PAIS. In some, especially those sufficiently virilized in infancy, the diagnosis is not suspected until puberty when there is inadequate virilization with lack of facial hair or voice change and the appearance of gynecomastia. Azoospermia and infertility are common. Increasingly, androgen receptor defects are being recognized in adults who have a small phallus and testes and infertility. A single-amino-acid substitution in the androgen receptor was reported in a large Chinese family in whom some affected members were fertile while others had gynecomastia and/or hypospadias. Production of insulin-like growth factor 2 and insulin-like growth factor–binding protein-2, but not insulin-like growth factor–binding protein-3, by genital skin fibroblasts is decreased in CAIS compared with normal genital skin fibroblasts, suggesting a possible role for the insulin-like growth factor system in modulating androgen action.

Table 588-5	Causes of a PAIS-Like Phenotype
DEFECTS IN ANDROGEN PRODUCTION • Partial gonadal dysgenesis • Mutations in *SRY, NR5A1, WT1* • Mutations of the luteinizing hormone receptor • Biosynthetic enzyme deficiencies • 17,20-Lyase deficiency • P450 oxidoreductase deficiency • 17β-hydroxysteroid dehydrogenase deficiency type 3 • 5α-Reductase deficiency type 2	
GENETIC • Klinefelter syndrome • Smith-Lemli-Opitz syndrome • Denys-Drash syndrome • Frasier syndrome	
PAIS • Mutations of the androgen receptor gene • Normal androgen receptor gene with fetal growth restriction	

NR5A1, nuclear receptor subfamily 5 A1; PAIS, partial androgen insensitivity syndrome; SRY, sex-determining region Y; WT1, Wilms tumor 1.

Treatment and Prognosis

In patients with CAIS whose sexual orientation is unambiguously female, the testes should be removed as soon as they are discovered. Laparoscopic removal of Y chromosome–bearing gonads has been performed in patients with AIS and in those with gonadal dysgenesis. In one third of patients, malignant tumors, usually seminomas, develop by 50 yr of age. Several teenage girls have acquired seminomas. Replacement therapy with estrogens is indicated at the age of puberty.

Normal breasts develop in affected girls who have not had their testes removed by the age of puberty. In these individuals, production of estradiol results from aromatase activity on testicular testosterone. The absence of androgenic activity also contributes to the feminization of these women.

The psychosexual and surgical management of patients with PAIS is extremely complex and depends in large part on the presenting phenotype. Osteopenia is recognized as a late feature of AIS.

Molecular analyses have suggested that phenotype may depend in part on somatic mosaicism of the androgen receptor gene. This was based on the case of a 46,XY patient who had a premature stop codon in exon 1 of the androgen receptor gene, but who also had evidence of virilization (pubic hair and clitoral enlargement) explained by the discovery of the wild-type alleles on careful examination of the sequencing gel. The presence of mosaicism shifts the phenotype to a higher degree of virilization than expected from the genotype of the mutant allele alone.

Genetic counseling is difficult in families with androgen receptor gene mutation. In addition to lack of genotype–phenotype correlations, there is a high rate (27%) of de novo mutations in families.

Sex hormone–binding globulin reduction after exogenous androgen administration (stanozolol) correlates with the severity of the receptor defect and may become a useful clinical tool. Successful therapy with supplemental androgens has been reported in patients with PAIS and various mutations of the androgen receptor in the DNA-binding domain and the ligand-binding domain.

Mutated androgen receptors are also reported in patients with spinal and bulbar muscular atrophy in whom clinical manifestations including testicular atrophy, infertility, gynecomastia, and elevated LH, follicle-stimulating hormone, and estradiol levels usually manifest between the 3rd and 5th decades of life. Androgen receptor mutations have also been described in patients with prostate cancer.

UNDETERMINED CAUSES

Other XY undervirilized males display great variability of the external and internal genitalia and various degrees of phallic and müllerian development. Testes may be histologically normal or rudimentary, or there may only be 1. No recognized cause is identified in up to 50% of children with 46,XY DSD. Some ambiguity of the genitalia is associated with a wide variety of chromosomal aberrations, which must always be considered in the differential diagnosis, the most common being the 45,X/46,XY syndrome (see Chapter 586.1). It may be necessary to karyotype several tissues to establish mosaicism. Other complex genetic syndromes, many resulting from single gene mutations, are associated with varying degrees of ambiguity of the genitalia, particularly in the male. These entities must be identified on the basis of the associated extragenital malformations.

Smith-Lemli-Opitz syndrome is an autosomal recessive disorder caused by mutations in the sterol Δ7-reductase gene located on chromosome 11q12-q13. It is characterized by prenatal and postnatal growth retardation, microcephaly, ptosis, anteverted nares, broad alveolar ridges, syndactyly of the 2nd-3rd toes, and severe cognitive impairment (see Chapter 86.3). Its incidence is 1 in 20,000 to 30,000 live births in populations of northern and central European origin; 70% are male. Genotypic males usually have genital ambiguity and, occasionally, partial sex reversal with female genital ambiguity or complete sex reversal with female external genitals. Müllerian duct derivatives are usually absent. Affected 46,XX patients have normal genitalia. Two types of Smith-Lemli-Opitz syndrome have been recognized. The **classical form** (type I) described earlier and the acrodysgenital syndrome, which is usually lethal within 1 yr and is associated with severe malformations, postaxial polydactyly, and extremely abnormal external genitalia (type II). Pyloric stenosis is associated with Smith-Lemli-Opitz syndrome type I and Hirschsprung disease with type II. Cleft palate, skeletal abnormalities, and 1 case of a lipoma of the pituitary gland have been seen in **type II** cases. Some authors believe in a spectrum of disease severity rather than in the above classification. Low plasma cholesterol with elevated 7-dehydrocholesterol, its precursor, are found in types I and II, and the levels do not correlate with severity. Maternal apolipoprotein E values do seem to correlate with severity. The most common prenatal expression of Smith-Lemli-Opitz syndrome is intrauterine growth retardation (see Chapter 86.3 for treatment).

46,XY DSD subjects also have been described in siblings with the α-thalassemia/mental retardation syndrome.

Bibliography is available at Expert Consult.

588.3 Ovotesticular DSD

Patricia A. Donohoue

In ovotesticular DSD, both ovarian and testicular tissues are present, either in the same or in opposite gonads. Affected patients have ambiguous genitalia, varying from normal female with only slight enlargement of the clitoris to almost normal male external genitalia (see Fig. 588-2*A*).

Approximately 70% of all patients have a 46,XX karyotype. Ninety-seven percent of affected patients of African descent are 46,XX. Fewer than 10% of persons with ovotesticular DSD are 46,XY. Approximately 20% have 46,XX/46,XY mosaicism. Half of these are derived from more than 1 zygote and are chimeras (chi 46,XX/46,XY). The presence of paternal and both maternal alleles for some blood groups is demonstrated. An ovotesticular DSD chimera, 46,XX/46,XY, was reported as resulting from embryo amalgamation after in vitro fertilization. Each embryo was derived from an independent, separately fertilized ovum.

Examination of 46,XX ovotesticular DSD patients with Y-specific probes has detected fewer than 10% with a portion of the Y chromosome including the *SRY* gene. Ovotesticular DSD is usually sporadic, but a number of siblings have been reported. The cause of most cases of ovotesticular DSD is unknown.

The most frequently encountered gonad in ovotesticular DSD is an ovotestis, which may be bilateral. If unilateral, the contralateral gonad

is usually an ovary but may be a testis. The ovarian tissue is normal, but the testicular tissue is dysgenetic. The presence and function of testicular tissue can be determined by measuring basal and hCG-stimulated testosterone levels as well as AMH levels. Patients who are highly virilized and have had adequate testicular function with no uterus are usually reared as males. If a uterus exists, virilization is often mild and testicular function minimal; assignment of female sex may be indicated. Selective removal of gonadal tissue inconsistent with sex of rearing may be indicated. In a few families, 46,XY ovotesticular DSD subjects and 44,XX males have been described in the same sibship.

Defects in R-Spondin1, encoded by the *RSPO1* gene, have been described in 46,XX ovotesticular DSD.

Pregnancies with living offspring have been reported in 46,XX ovotesticular DSD individuals reared as females, but very few males with ovotesticular DSD have fathered children. Approximately 5% of patients will develop gonadoblastomas, dysgerminomas, or seminomas.

DIAGNOSIS AND MANAGEMENT OF DISORDERS OF SEX DEVELOPMENT

In the neonate, ambiguity of the genitals requires immediate attention to decide on the sex of rearing as early in life as possible. The family of the infant needs to be informed of the child's condition as early, completely, compassionately, and honestly as possible. Caution must be used to avoid feelings of guilt, shame, and discomfort. Guidance needs to be provided to alleviate both short-term and long-term concerns and to allow the child to grow up in a completely supportive environment. The initial care is best provided by a team of professionals that include neonatologists and pediatric specialists, endocrinologists, radiologists, urologists, psychologists, and geneticists, all of whom remain focused foremost on the needs of the child. Management of the potential psychologic upheaval that these disorders can generate in the child or the family is of paramount importance and requires physicians and other healthcare professionals with sensitivity, training, and experience in this field.

While awaiting the results of chromosomal analysis, pelvic ultrasonography is indicated to determine the presence of a uterus and ovaries. Presence of a uterus and absence of palpable gonads usually suggests a virilized XX female. A search for the source of virilization should be undertaken; this includes studies of adrenal hormones to rule out varieties of congenital adrenal hyperplasia, and studies of androgens and estrogens occasionally may be necessary to rule out aromatase deficiency. Virilized XX females are generally (but not always) reared as females even when highly virilized.

The absence of a uterus, with or without palpable gonads, often indicates an undervirilized male and an XY karyotype. Measurements of levels of gonadotropins, testosterone, AMH, and DHT are necessary to determine whether testicular production of androgen is present and is normal. Undervirilized males who are totally feminized may be reared as females. Certain significantly feminized infants, such as those with 5α-reductase deficiency, may be reared as males because these children virilize normally at puberty. Sixty percent of individuals with 5α-reductase deficiency assigned as female in infancy live as males as adults. An infant with a comparable degree of feminization resulting from an androgen receptor defect, such as CAIS, is best reared as a female.

When receptor disorders are suspected in the XY male with a small phallus (micropenis), a course of 3 monthly intramuscular injections of testosterone enanthate (25-50 mg) may assist in the differential diagnosis of androgen insensitivity, as well as in treatment.

In some mammals, the female exposed to androgens prenatally or in early postnatal life exhibits nontraditional sexual behavior in adult life. Most, but not all, girls who have undergone fetal masculinization from congenital adrenal hyperplasia or from maternal progestin therapy have female sexual identity, although during childhood they may appear to prefer male playmates and activities over female playmates and feminine play with dolls in mothering roles.

In the past it was thought that surgical treatment of ambiguous genitalia to create a female appearance, particularly when a vagina is present, was more successful than construction of male genitalia. Considerable controversy exists regarding these decisions. Sexual functioning is to a large extent more dependent on neurohormonal and behavioral factors than the physical appearance and functional ability of the genitalia. Similarly, controversy exists regarding the timing of the performance of invasive and definitive procedures, such as surgery. Whenever possible without endangering the physical or psychologic health of the child, an expert multidisciplinary team should consider deferring elective surgical repairs and gonadectomies until the child can participate in the informed consent for the procedure. One study of children (n = 59 boys and 18 girls) with gender dysphoria but without documentation of genomic or enzymologic abnormalities indicated that most of these children no longer have gender dysphoria after completion of puberty. Among those who do, homosexuality and bisexuality are the most frequent diagnoses.

For patients with DSD who have Y-chromosome material and intraabdominal gonads, gonadectomy is generally recommended because of the risk of gonadal tumors, many of which are malignant.

The pediatrician, pediatric endocrinologist, and psychologist, along with the appropriate additional specialists, should provide ongoing compassionate, supportive care to the patient and the patient's family throughout childhood, adolescence, and adulthood. Support groups are available for families and patients with many of the conditions discussed.

Diabetes Mellitus in Children

Chapter 589 Diabetes Mellitus

589.1 Classification

Britta M. Svoren and Nicholas Jospe

Diabetes mellitus (DM) is a common, chronic, metabolic disease characterized by hyperglycemia as a cardinal biochemical feature. The major forms of diabetes are differentiated by insulin deficiency vs insulin resistance: type 1 diabetes mellitus (T1DM) results from deficiency of insulin secretion because of pancreatic β-cell damage; type 2 diabetes mellitus (T2DM) is a consequence of insulin resistance occurring at the level of skeletal muscle, liver, and adipose tissue, with various degrees of β-cell impairment. T1DM is the most common endocrine-metabolic disorder of childhood and adolescence, with important consequences for physical and emotional development. Individuals with T1DM confront serious lifestyle alterations, including an absolute daily requirement for exogenous insulin, the need to monitor their own glucose level, and the need to pay attention to dietary intake. Morbidity and mortality stem from a constant potential for acute metabolic derangements and from long-term **complications** (usually in adulthood) that affect small and large blood vessels resulting in retinopathy, nephropathy, neuropathy, ischemic heart disease, and arterial obstruction with gangrene of the extremities. The acute clinical manifestations are caused by hypoinsulinemic hyperglycemic ketoacidosis; the genesis of T1DM owes to autoimmune mechanisms; and the long-term complications are related to metabolic disturbances (hyperglycemia).

Table 589-1 Etiologic Classifications of Diabetes Mellitus

I. Type 1 diabetes (β-cell destruction ultimately leading to complete insulin deficiency)
  A. Immune mediated
  B. Idiopathic
II. Type 2 diabetes (variable combinations of insulin resistance and insulin deficiency)
  A. Typical
  B. Atypical
III. Genetic defects of β-cell function
  A. MODY (maturity-onset diabetes of the young) syndromes
    1. MODY 1 chromosome 20, HNF4α
    2. MODY 2 chromosome 7, glucokinase
    3. MODY 3 chromosome 12, HNF1α, TCF-1
    4. MODY 4 chromosome 13, IPF-1
    5. MODY 5 chromosome 17, HNF1β, TCF-2
    6. MODY 6 chromosome 2q32, neuro-D_1/β_2
  B. Mitochondrial DNA mutations (includes 1 form of Wolfram syndrome, Pearson syndrome, Kearns-Sayre, diabetes mellitus, deafness)
  C. Wolfram syndrome—DIDMOAD (diabetes insipidus, diabetes mellitus, optic atrophy, deafness): WFS1-Wolframin—chromosome 4p
    1. Wolfram locus 2—chromosome 4q22-24
    2. Wolfram mitochondrial
  D. Thiamine responsive megaloblastic anemia and diabetes
IV. Drug or chemical induced
  A. Antirejection—cyclosporine, sirolimus
  B. Glucocorticoids (with impaired insulin secretion; e.g., cystic fibrosis)
  C. L-Asparaginase
  D. β-Adrenergic blockers
  E. Vacor (rodenticide)
  F. Phenytoin (Dilantin)
  G. α-Interferon
  H. Diazoxide
  I. Nicotinic acid
  J. Pentamidine
V. Diseases of exocrine pancreas
  A. Cystic fibrosis–related diabetes
  B. Trauma—pancreatectomy
  C. Pancreatitis—ionizing radiation
  D. Others
VI. Infections
  A. Congenital rubella
  B. Cytomegalovirus
  C. Hemolytic-uremic syndrome
VII. Variants of type 2 diabetes
  A. Genetic defects of insulin action
    1. Rabson-Mendenhall syndrome
    2. Leprechaunism
    3. Lipoatrophic diabetes syndromes
    4. Type A insulin resistance—acanthosis
  B. Acquired defects of insulin action
    1. Endocrine tumors—rare in childhood
  C. Pheochromocytoma
  D. Cushing
  E. Others
    1. Antiinsulin receptor antibodies
VIII. Genetic syndromes with diabetes and insulin resistance/insulin deficiency
  A. Prader-Willi syndrome, chromosome 15
  B. Down syndrome, chromosome 21
  C. Turner syndrome
  D. Klinefelter syndrome
  E. Others
    1. Bardet-Biedel
    2. Alström
    3. Werner
  F. IPEX (immunodysfunction, polyendocrinopathy, enteropathy, X-linked)
  G. Celiac disease
  H. Autoimmune polyendocrinopathy
IX. Gestational diabetes
X. Neonatal diabetes
  A. Transient—chromosome 6q24, KCNJ11, ABCC8, INS, HNF1β, others
  B. Permanent—agenesis of pancreas—glucokinase deficiency, homozygous, KCNJ11, ABCC8, others

Modified from Sperling MA, Tamborlane WV, Battelino T, Weinzimer SA, Phillip M: Diabetes mellitus. In Sperling MA, editor: Pediatric endocrinology, *ed 4, Philadelphia, 2014, Elsevier, Box 19-1.*

DM is not a single entity but rather a heterogeneous group of disorders in which there are distinct genetic patterns as well as other etiologic and pathophysiologic mechanisms that lead to impairment of glucose tolerance. Table 589-1 presents a classification of diabetes and other categories of glucose intolerance. Three major forms of diabetes and several forms of carbohydrate intolerance are identified.

TYPE 1 DIABETES MELLITUS

Formerly called *insulin-dependent diabetes mellitus* (IDDM) or *juvenile diabetes*, T1DM is characterized by low or absent levels of endogenously produced insulin and by dependence on exogenous insulin to prevent development of ketoacidosis, an acute life-threatening complication of T1DM. The natural history includes 4 distinct stages: (1) preclinical β-cell autoimmunity with progressive defect of insulin secretion, (2) onset of clinical diabetes, (3) transient remission "honeymoon period," and (4) established diabetes during which there may occur acute and/or chronic complications and decreased life expectancy. The onset occurs predominantly in childhood, with a median age of 7-15 yr, but it may present at any age. The incidence of T1DM has steadily increased in nearly all parts of the world (Fig. 589-1). T1DM is characterized by autoimmune destruction of pancreatic islet β cells. Both genetic susceptibility and environmental factors contribute to the pathogenesis. Susceptibility to T1DM is genetically controlled by alleles of the major histocompatibility complex class II genes expressing human leukocyte antigens (HLAs). Autoantibodies to β-cell antigens such as islet cell cytoplasm (ICA), insulin autoantibody (IAA), antibodies to glutamic acid decarboxylase, and ICA512 are detected in serum from affected subjects. These can be detected months to years prior to clinical onset of T1DM. T1DM is associated with other **autoimmune** diseases such as thyroiditis, celiac disease, and Addison disease. In some children and adolescents with apparent T1DM, the β-cell destruction is not immune mediated. This subtype of diabetes occurs in patients of African or Asian origin and is distinct from known causes of β-cell destruction such as drugs or chemicals, viruses, mitochondrial gene defects, pancreatectomy, and ionizing radiation. These individuals may have ketoacidosis, but they have extensive periods of remission with variable insulin deficiency, similar to patients with T2DM.

TYPE 2 DIABETES MELLITUS

Children and adolescents with this type of diabetes are usually obese but are not insulin dependent and infrequently develop ketosis. Some subjects with T2DM may present with or develop ketosis during severe infections or other stresses and may then need insulin for correction of symptomatic hyperglycemia. This category includes the most prevalent form of diabetes in adults, which is characterized by insulin

resistance and often a progressive defect in insulin secretion. This type of diabetes was formerly known as *adult-onset diabetes mellitus or non–insulin-dependent diabetes mellitus*.

The presentation of T2DM is typically more insidious than that with T1DM. In contrast to patients with T1DM who are usually ill at the time of diagnosis and whose presentation rarely spans more than a few weeks, children with T2DM often seek medical care because of excessive weight gain and fatigue as a result of insulin resistance and/or the incidental finding of glycosuria during routine physical examination. A history of polyuria and polydipsia is not always a cardinal clinical feature in these patients. The incidence of T2DM in children has increased by more than 10-fold, depending on geography and mostly as a result of the epidemic of childhood obesity (see Chapter 47). Pediatric T2DM may account for as many as 80% of the new cases of diabetes, especially in obese African-American and Mexican-American adolescents. **Acanthosis nigricans** (dark pigmentation of skin creases in the nape of the neck especially), a sign of insulin resistance, is present in the majority of patients with T2DM and is accompanied by a relative hyperinsulinemia at the time of the diagnosis (see Chapter 652). However, the serum insulin elevation is usually disproportionately lower than that of age-, weight-, and sex-matched nondiabetic children and adolescents, suggesting a state of insulin insufficiency. In some individuals, it may represent slowly evolving T1DM.

In some children with a strong family history of diabetes, impaired glucose tolerance (IGT) may occur in a pattern implying dominant inheritance. This pattern of diabetes has been termed **maturity-onset diabetes of the young (MODY):** it may require insulin treatment, can be treated with sulfonylureas with varying degrees of success, and is often now referred to as monogenic diabetes. MODY may present with hyperglycemia, and consequent polyuria and polydipsia, or may be diagnosed simply by routine screening. In MODY, there is no autoimmune destruction of β cells and no HLA association. MODY results from specific genetic disorders involving mutations in the gene encoding either pancreatic β-cell and liver glucokinase or in the nuclear transcription factors hepatocyte nuclear factor (1α, 4α, or 1β). A defect in the gene regulating glucose transport into the pancreatic β cell, the GLUT2 transporter, may be responsible for other forms of T2DM. The genetic basis of T2DM also includes defects in glycogen synthase, insulin receptors, Rad (Ras associated with diabetes), and possibly apolipoprotein C-III. A recent metaanalysis suggests that the incidence of T2DM has a complexly inverse relationship with birthweight in some populations, depending on ethnic and genetic factors.

OTHER SPECIFIC TYPES OF SECONDARY DIABETES

Examples include diabetes secondary to exocrine pancreatic diseases (cystic fibrosis), other endocrine diseases (Cushing syndrome), and ingestion of certain drugs or poisons (the rodenticide Vacor). In organ transplantation survivors, there is a linkage between cyclosporine and tacrolimus and posttransplantation DM, ascribed to a number of mechanisms. Certain genetic syndromes, including those with abnormalities of the insulin receptor, also are included in this category. There are no associations with HLA types, autoimmunity, or islet cell antibodies among the entities in this subdivision.

Table 589-2 details the current criteria for the diagnosis of type 1 and type 2 DM. It should be noted that a fasting blood glucose that exceeds 125 mg/dL (6.9 mmol/L) is the accepted criterion for the diagnosis of diabetes.

IMPAIRED GLUCOSE TOLERANCE

The term *impaired glucose tolerance* (IGT) refers to a metabolic stage that is intermediate between normal glucose homeostasis and diabetes. A fasting glucose concentration of 99 mg/dL (5.5 mmol/L) is the upper limit of "normal." This choice is near the level above which acute-phase insulin secretion is lost in response to intravenous administration of glucose and is associated with a progressively greater risk of the development of microvascular and macrovascular complications.

Many individuals with IGT (fasting glucose 100-125 mg/dL) are euglycemic in their daily lives and may have normal or nearly normal glycated hemoglobin levels. Individuals with IGT often manifest hyperglycemia only when challenged with the oral glucose load used in the standardized oral glucose tolerance test.

In the absence of pregnancy, IGT is not a clinical entity but rather a risk factor for future diabetes and cardiovascular disease. This may be observed as an intermediate stage in any of the disease processes listed in Table 589-1. IGT is often associated with the **insulin**

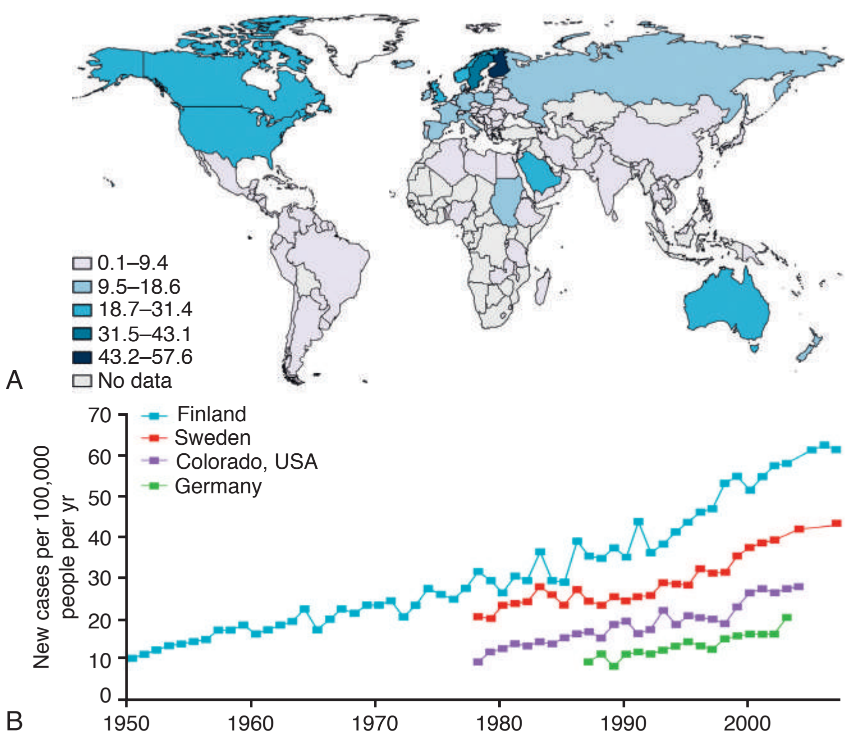

Figure 589-1 Incidence of type 1 diabetes in children ages 0-14 yr, by geographical region and over time. **A,** Estimated global incidence of type 1 diabetes, by region, in 2011. **B,** Time-based trends for the incidence of type 1 diabetes in children ages 0-14 yr in areas with high or high-intermediate rates of disease. *(From Atkinson MA, Eisenbarth GS, Michels AW: Type 1 diabetes.* Lancet *383:69–78, 2014, Fig. 1, p. 70.)*

Table 589-2	Diagnostic Criteria for Impaired Glucose Tolerance and Diabetes Mellitus
IMPAIRED GLUCOSE TOLERANCE	**DIABETES MELLITUS**
Fasting glucose 100-125 mg/dL (5.6-7.0 mmol/L)	Symptoms* of diabetes mellitus plus random or casual plasma glucose ≥200 mg/dL (11.1 mmol/L)
	or
2-hr plasma glucose during the OGTT ≥140 mg/dL, but <200 mg/dL (11.1 mmol/L)	Fasting (at least 8 hr) plasma glucose ≥126 mg/dL (7.0 mmol/L) *or* 2 hr plasma glucose during the OGTT ≥200 mg/dL *or* Hemoglobin A_{1C} ≥6.5%[†]

*Symptoms include polyuria, polydipsia, and unexplained weight loss with glucosuria and ketonuria.
[†]Results should be confirmed by repeat testing if in absence of unequivocal hyperglycemia.
OGTT, oral glucose tolerance test.
From Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus, Diabetes Care *20(Suppl 1):S5, 1999; and from Chaing J, Kirkman S, Laffel L, et al: Type 1 diabetes through the life span: A position statement of the American Diabetes Association,* Diabetes Care *37:2034–2054, 2014.*

resistance syndrome (also known as *syndrome X* or *metabolic syndrome*), which consists of insulin resistance, compensatory hyperinsulinemia to maintain glucose homeostasis, obesity (especially abdominal or visceral obesity), dyslipidemia of the high-triglyceride or low- or high-density lipoprotein type, or both, and hypertension (see Chapter 47). Insulin resistance is directly involved in the pathogenesis of T2DM. IGT appears as a risk marker for this type of diabetes at least in part because of its correlation with insulin resistance. Table 589-2 presents the diagnostic criteria for IGT.

589.2 Type 1 Diabetes Mellitus (Immune Mediated)

Britta M. Svoren and Nicholas Jospe

EPIDEMIOLOGY

T1DM accounts for approximately 10% of all cases of diabetes, affecting up to 3 million people in the United States and more than 15 million people in the world. Using population-based estimates of diabetes incidence and prevalence, a recent study indicates that approximately 15,000 youths are diagnosed with type 1 diabetes each year. While it accounts for most cases of diabetes in childhood, it is not limited to this age group; new cases continue to occur in adult life and approximately 50% of individuals with T1DM present as adults. The incidence of T1DM is highly variable among different ethnic groups (see Fig. 589-1). The overall age-adjusted incidence of T1 DM varies from 0.7 in 100,000 per yr in Karachi (Pakistan) to more than 40 in 100,000 per yr in Finland. The incidence of T1DM is increasing in most (but not all) populations and this increase appears to be most marked in populations where the incidence of autoimmune diseases was historically low. Data from Western European diabetes centers suggest that the annual rate of increase in T1DM incidence is 2-5%, whereas some central and eastern European countries demonstrate an even more rapid increase—up to 9%. The rate of increase is greatest among the youngest children. In the United States, the overall prevalence of diabetes among school-age children is approximately 1.9 in 1,000, increasing from a prevalence of 1 in 1,430 children at 5 yr of age to 1 in 360 children at 16 yr of age. Among African-Americans, the occurrence of T1DM is 30-60% of that seen in American whites. The annual incidence of new cases in the United States is now approximately 19.7 in 100,000 among youth younger than 10 yr and 18.6 in 100,000 of those older than 10 yr, It is estimated that 30,000 new cases occur each year in the United States, affecting 1 in 300 children and as many as 1 in 100 adults during the life span. Rates are similar or higher in most Western European countries and significantly lower in Asia and Africa.

Girls and boys are almost equally affected, but there is a modest female preponderance in some low-risk populations (e.g., the Japanese); there is no apparent correlation with socioeconomic status. Peaks of presentation occur in 2 age groups: at 5-7 yr of age and at the time of puberty. The first peak may correspond to the time of increased exposure to infectious agents coincident with the beginning of school; the second peak may correspond to the pubertal growth spurt induced by gonadal steroids and the increased pubertal growth hormone secretion (which antagonizes insulin). The understanding of the cause of diabetes or of its increased incidence remains elusive. A growing number of cases are presenting between 1 and 2 yr of age, especially in high-risk groups; the average age of presentation is older in low-risk populations. Low-risk groups that migrate to a high-risk country seem to acquire the increased risk of that country. On the other hand, there can be marked differences in incidence rates in various ethnic groups within the same country; for example, incidence rates in the 10-14 yr age group in the United States range from a low of 7.1 in Native Americans, to 17.6 in Hispanics, 19.2 in African-Americans, and 32.9 in whites. These variations also remain unexplained at this time.

GENETICS

There is a clear familial clustering of T1DM, with prevalence in siblings approaching 6%, whereas the prevalence in the general population in the United States is only 0.4%. Risk of diabetes is also increased when a parent has diabetes and this risk differs between the 2 parents; the risk is 3-4% if the mother has diabetes but 5-6% when the father has diabetes. In monozygotic twins, the concordance rate ranges from 30-65%, whereas dizygotic twins have a concordance rate of 6-10%. Because the concordance rate of dizygotic twins is higher than the sibling risk, factors other than the shared genotypes (e.g., the shared intrauterine environment) may play a role in increasing the risk in dizygotic twins. Furthermore, the genetic susceptibility for T1DM in the parents of a child with diabetes is estimated at 3%. It should be kept in mind that although there is a large genetic component in T1DM, 85% of newly diagnosed type 1 diabetic patients do not have a family member with T1DM. Thus, we cannot rely on family history to identify patients who may be at risk for the future development of T1DM as most cases will develop in individuals with no such family history.

Monogenic Type 1 Diabetes Mellitus

Classic single-gene defects are an extremely rare cause of type 1 diabetes, and more than 20 genes have been linked to monogenic diabetes, in children and in adults. In 2 rare syndromes (IPEX and APS-1) the genetic susceptibility that leads to diabetes is caused by a classic single-gene defect. The IPEX (immune dysfunction, polyendocrinopathy, enteropathy, X-linked) syndrome is caused by mutations of the *FOXP3* and other genes. The *FOXP3* (forkhead box P3) is a gene involved in immune system responses. A member of the FOX protein family, *FOXP3* appears to function as the master regulator in the development and function of regulatory T cells. These mutations lead to the lack of a major population of regulatory T lymphocytes with resulting overwhelming autoimmunity and development of diabetes (as early as 2 days of age) in approximately 80% of the children with this disorder.

APS-1 (autoimmune polyendocrinopathy syndrome type 1) is caused by mutations of the *AIRE* (autoimmune regulator) gene, leading to abnormalities in expression of peripheral antigens within the thymus and/or abnormalities of negative selection in the thymus. This results in widespread autoimmunity. Approximately 18% of children with this syndrome develop type 1 diabetes.

Genes Altering the Risk of Autoimmune Type 1 Diabetes Mellitus

For most patients with T1DM, their risk of developing T1DM is modified by the influence of several risk loci. The genomic region with by

far the greatest contribution to the risk of T1DM is the major histocompatibility complex on chromosome 6. The region with the next highest odds ratio is the promoter region 5′ of the insulin gene on chromosome 11. Studies have identified more than 50 other risk loci. These loci include insulin *(INS)*, protein tyrosine phosphatase nonreceptor type 22 *(PTPN22)*, protein tyrosine phosphatase nonreceptor type 2 *(PTPN2)*, interleukin (IL)-2 receptor *(CD25)*, a lectin-like gene *(KIAA0350)*, v-erb-b2 erythroblastic leukemia viral oncogene homolog 3e *(ERBB3e)*, cytotoxic T-lymphocyte antigen 4 *(CTLA4)*, and interferon-induced with helicase C domain 1 *(IFIH1)*. However, except for *PTPN22*, their contribution is relatively small, thus making them less useful for predicting the genetic risk of T1DM in a given individual. On balance, the known functions of these genes suggest the primary etiologic pathways of diabetes, namely, HLA class II and class I molecules binding, T and B cell activation, innate pathogen viral responses, chemokine and cytokine signaling, and T regulatory and antigen-presenting cell functions.

Major Histocompatibility Complex/Human Leukocyte Antigen Encoded Susceptibility to Type 1 Diabetes Mellitus

The major histocompatibility complex is a large genomic region that contains a number of genes related to immune system function in humans. These genes are further divided into HLA classes I, II, III, and IV genes. Class II genes are the ones most strongly associated with risk of T1DM, but some of the risk associated with various HLA types is a result of variation in genes in HLA classes other than class II. Overall, genetic variation in the HLA region can explain 40-50% of the genetic risk of T1DM (Fig. 589-2).

Some of the known associations include the HLA DR3/4-DQ2/8 genotype; compared to a population prevalence of T1DM of approximately 1 in 300, DR3/4-DQ2/8 newborns from the general population have a 1 in 20 genetic risk. This risk of development of T1DM is even higher when the high-risk HLA haplotypes are shared with a sibling or parent with T1DM. Thus, if 1 sibling has T1DM and shares the same high-risk DR3/4-DQ2/8 haplotype with another sibling, then the risk of autoimmunity in the other sibling is 50%. And this risk approaches 80% when siblings share both HLA haplotypes identical by descent. This is known as the *relative paradox* and points to the existence of other shared genetic risk factors (most likely in the extended HLA haplotype).

With advances in genotyping, further discrimination is possible and we can identify more specific risk ratios for specific haplotypes. For example, the DRB1*0401-DQA1*0301g-DQB1*0302 haplotype has an odds ratio (OR) of 8.39 whereas the DRB1*0401-DQA1*0301g-DQB1*0301 has an OR of 0.35, implicating the DQB1*0302 allele as a critical susceptibility allele. There are some dramatically protective

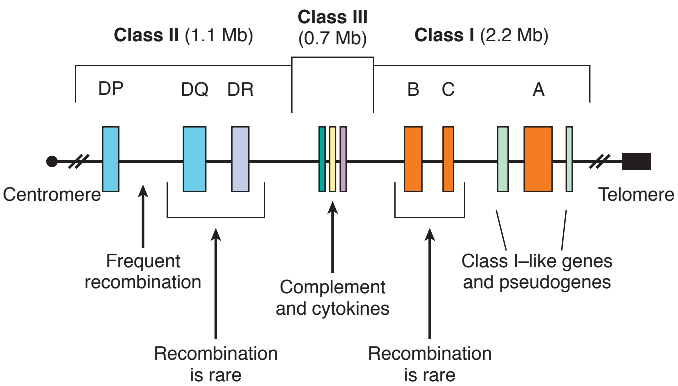

Figure 589-2 The human leukocyte antigen (HLA) complex (6p21.31). Graphic representation of the HLA complex, showing the relative locations of the 3 classes of HLA genes. *(Courtesy of Dr. George Eisenbarth.)*

DR-DQ haplotypes (e.g., DRB1*1501-DQA1*0102-DQB1*0602 [OR = 0.03], DRB1*1401-DQA1*0101-DQB1*0503 [OR = 0.02], and DRB1*0701-DQA1*0201-DQB1*0303 [OR = 0.02]). The DR2 haplotype (DRB1*1501-DQA1*0102-DQB1*0602) is dominantly protective and is present in 20% of the general population but is seen in only 1% of patients with T1DM.

Role of Aspartate at Position 57 in DQB1

DQB1*0302 (high risk for diabetes) differs from DQB1*0301 (protective against diabetes) only at position 57, where it lacks an aspartic acid residue. The DQB1*0201 allele (increased risk for diabetes) also lacks aspartic acid at position 57, and it has been proposed that the presence of aspartate at this position alters the protein recognition and protein binding characteristics of this molecule. Although the absence of aspartate at this position appears to be important in most studies on white individuals, it does not have the same role in Korean and Japanese populations. Moreover, certain low-risk DQB1 genotypes also lack aspartic acid at position 57, including DQB1*0302/DQB1*0201 (DR7) and DQB1*0201 (DR3)/DQB1*0201 (DR7). Thus, the presence of aspartate at this position is usually, but not always, protective in white populations but not necessarily in other populations.

Role of Human Leukocyte Antigen Class I

Although the alleles of class II HLA genes appear to have the strongest associations with diabetes, recent genotyping studies and analyses of pooled data have identified associations with other elements in the HLA complex, especially HLA-A and HLA-B. The most significant association is with HLA-B39, which confers high risk for T1DM in 3 different populations, makes up the majority of the signal from HLA-B, and is associated with a lower age of onset of the disease.

Insulin Gene Locus, *IDDM2*

The second locus found to be associated with risk of T1DM was labeled IDDM2 and has been localized to a region upstream of the insulin gene (i.e., 5′ of the insulin gene). It is estimated that this locus accounts for approximately 10% of the familial risk of T1DM. Susceptibility in this region has been primarily mapped to a variable number of tandem repeats approximately 500 bp upstream of the insulin gene. This highly polymorphic region consists of anywhere from 30 to several hundred repeats of a 14-15 bp unit sequence (ACAGGGGTCTGGGG). A shorter number of repeats is associated with increased risk of T1DM.

PTPN22 (Lymphoid Tyrosine Phosphatase)

A single-nucleotide polymorphism in the *PTPN22* gene on chromosome 1p13 that encodes lymphoid tyrosine phosphatase correlates strongly with the incidence of T1DM in 2 independent populations. This gene has an association with several other autoimmune diseases such as rheumatoid arthritis, systemic lupus erythematosus, vitiligo, and Graves disease.

Cytotoxic T Lymphocyte Antigen 4

The cytotoxic T lymphocyte antigen 4 *(CTLA-4)* gene is located on chromosome 2q33 and is associated with T1DM as well as Graves disease, Hashimoto thyroiditis, celiac disease, and systemic lupus erythematosus. This gene is a negative regulator of T-cell activation.

Interleukin-2 Receptor

Single-nucleotide polymorphisms in or near the gene for the IL-2 receptor have been found to have an association with T1DM risk. Studies with IL-2 in T1DM to date have not been successful in halting progression.

Interleukin-1 Receptor

IL-1 receptor activation and chemokines involved in monocyte/macrophage and neutrophil chemotaxis have been also identified as critical steps in nitric oxide–induced islet necrosis and subsequent apoptosis. Indeed, inhibition of the activation of IL-1β–dependent inflammatory pathways by an IL-1 receptor antagonist in cultured rat islets exposed to nitric oxide prevented necrosis and apoptosis

supporting evaluation in human islets in vitro and potentially as a posttransplantation therapy. **IL-1 blockade in patients with T1DM has not halted progression.**

Interferon-Induced Helicase

Another gene identified as having a modest effect on the risk of T1DM is the interferon-induced helicase *(IFIH1)* gene. Significant association exists with T1DM as well as Graves disease and multiple sclerosis. This gene is thought to play a role in protecting the host from viral infections and given the specificity of different helicases for different RNA viruses, it is possible that knowledge of this gene locus will help to narrow down the list of viral pathogens that may have a role in T1DM.

CYP27B1

Cytochrome P450, subfamily 27, polypeptide 1 gene encodes vitamin D 1α-hydroxylase. Because of the known role of vitamin D in immune regulation and because of epidemiologic evidence that vitamin D may play a role in T1DM, this gene was examined as a candidate gene and 2 single-nucleotide polymorphisms were found to be associated.

ENVIRONMENTAL FACTORS

That 50% or so of monozygotic twins are discordant for T1DM, the variation seen in urban and rural areas populated by the same ethnic group, the change in incidence that occurs with migration, the increase in incidence that has been seen in almost all populations in the last few decades, and the occurrence of seasonality all provide evidence that environmental factors also play a significant role in the causation of T1DM.

Viral Infections

It is possible that various viruses do play a role in the pathogenesis of T1DM, but no single virus, and no single pathogenic mechanism, stands out in the environmental etiology of T1DM. Instead, a variety of viruses and mechanisms may contribute to the development of diabetes in genetically susceptible hosts. Invoked mechanisms involved direct infection of β cells by viruses resulting in lysis and release of self-antigens, direct viral infection of antigen-presenting cells causing increased expression of cytokines, and "molecular mimicry," the notion that viral antigens exhibit homology to self-epitopes.

Congenital Rubella Syndrome

The clearest evidence of a role for viral infection in human T1DM is seen in congenital rubella syndrome. Prenatal infection with rubella is associated with β-cell autoimmunity in up to 70%, with development of T1DM in up to 40% of infected children. The time lag between infection and development of diabetes may be as high as 20 yr. T1DM after congenital rubella is more likely in patients that carry the higher-risk genotypes. Interestingly, there appears to be no increase in risk of diabetes when rubella infection develops after birth or when live-virus rubella immunization is used.

Enteroviruses

Studies show an increase in evidence of enteroviral infection in patients with T1DM and an increased prevalence of enteroviral RNA in prenatal blood samples from children who subsequently develop T1DM. In addition, there are case reports of association between enteroviral infection and subsequent T1DM. But the true significance of these infections remains unknown at this time.

Mumps Virus

It has been variably observed that mumps infection leads to the development of β-cell autoimmunity with high frequency and to T1DM in some cases. Although mumps may play a role in some cases of diabetes, the fact that T1DM diabetes incidence has increased steadily in several countries after universal mumps vaccination was introduced and that the incidence is extremely low in several populations where mumps is still prevalent indicates that mumps alone is not a major causal factor in diabetes.

The Hygiene Hypothesis: Possible Protective Role of Infections

Although some viral infections may increase the risk of T1DM, infectious agents may also play a protective role against diabetes. The hygiene hypothesis states that T1DM is a disease of industrialized countries, where the observation that there are fewer infections implies that the immune system is less-well trained for its main task, namely host defense. Some call this theory the "microbial deprivation hypothesis." The hygiene hypothesis states that lack of exposure to childhood infections may increase an individual's chances of developing autoimmune diseases, including T1DM. Rates of T1DM and other autoimmune disorders are generally lower in underdeveloped nations with a high prevalence of childhood infections and tend to increase as these countries become more developed. The incidence of T1DM differs almost 6-fold between Russian Karelia and Finland, even though both are populated by a genetically related population and are adjacent to each other and at the same latitude. The incidence of autoimmunity in the 2 populations varies inversely with immunoglobulin (Ig) E antibody levels, and IgE is involved in the response to parasitic infestation. All these observations indicate that decreased exposure to certain parasites and other microbes in early childhood may lead to an increased risk of autoimmunity in later life, including autoimmune diabetes. On the other hand, retrospective case-control studies have been equivocal at best and direct evidence of protection by childhood infections is still lacking.

Diet

Breastfeeding may lower the risk of T1DM, either directly or by delaying exposure to cow's milk protein. Early introduction of cow's milk protein and early exposure to gluten are implicated in the development of autoimmunity and it has been suggested that this is a result of the "leakiness" of the immature gut to protein antigens. Implicated antigens include β-lactoglobulin, a major lipocalin protein in bovine milk, which is homologous to the human protein glycodelin (PP14), a T-cell modulator. Other studies focused on bovine serum albumin as the inciting antigen, but the data are contradictory and not yet conclusive. In addition, milk and milk products are also indicators of the level of contamination of persistent organic pollutants, polychlorinated biphenyls, dioxin, and others. One large study in infants who are at high risk for T1DM did not demonstrate a reduced incidence of diabetes-associated autoantibodies when fed an extensively hydrolyzed vs cow milk–based formula. A smaller study demonstrated a reduced incidence of autoantibody production in infants fed a whey-based formula that was free of bovine insulin. Additional studies are underway and should be available in 2017.

Other dietary factors that have been suggested at various times as playing a role in diabetes risk include omega-3 fatty acids, vitamin D, ascorbic acid, zinc, and vitamin E. Vitamin D is biologically plausible (it has a role in immune regulation), deficiency is more common in northern countries like Finland, and there is some epidemiologic evidence that decreased vitamin D levels in pregnancy or early childhood may be associated with diabetes risk; but the evidence is not yet conclusive and it is hoped that ongoing studies like TEDDY (The Environmental Determinants of Diabetes in the Young) will help to resolve some of the uncertainties in this area.

Psychologic Stress

Several studies show an increased prevalence of stressful psychologic situations among children who subsequently developed T1DM. Whether these stresses only aggravate preexisting autoimmunity or whether they can actually trigger autoimmunity through epigenetic mechanisms remains unknown.

PATHOGENESIS AND NATURAL HISTORY OF TYPE 1 DIABETES MELLITUS

In T1DM, a genetically susceptible host develops autoimmunity against the host's own β cells. What triggers this autoimmune response remains unclear at this time. In some (but not all) patients, this autoimmune process results in progressive destruction of β cells until a critical mass

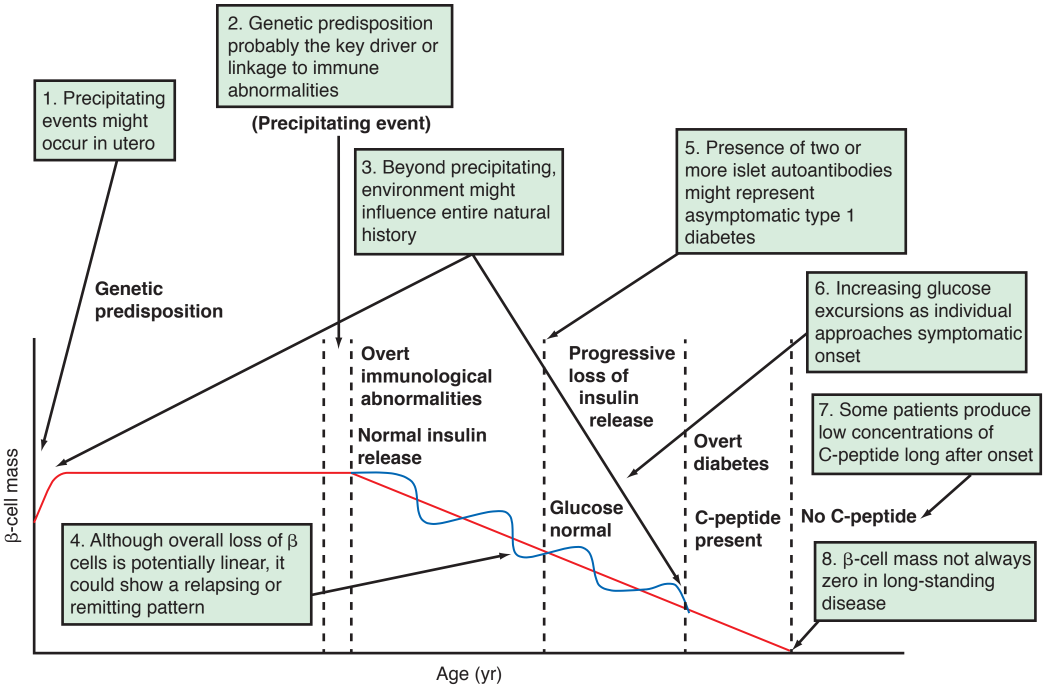

Figure 589-3 **The natural history of type 1 diabetes—a 25 yr old concept revisited.** A recreation of the model of type 1 diabetes, originally proposed in 1986, is shown in *black*. Additions and conjectures based on recent knowledge gains are shown in *green*. *(From Atkinson MA, Eisenbarth GS, Michels AW: Type 1 diabetes.* Lancet *383:69–78, 2014, Fig. 4, p. 73.)*

of β cells is lost and insulin deficiency develops. Insulin deficiency, in turn, leads to the onset of clinical signs and symptoms of T1DM. At the time of diagnosis, some viable β cells are still present and these may produce enough insulin to lead to a partial remission of the disease (honeymoon period) but over time, almost all β cells are destroyed and the patient becomes totally dependent on exogenous insulin for survival (Fig. 589-3). Over time, some of these patients develop secondary complications of diabetes that appear to be related to how well-controlled the diabetes has been. Thus, the natural history of T1DM involves some or all of the following stages:

1. Initiation of autoimmunity
2. Preclinical autoimmunity with progressive loss of β-cell function
3. Onset of clinical disease
4. Transient remission
5. Established disease
6. Development of complications

Initiation of Autoimmunity

Genetic susceptibility to T1DM is determined by several genes (see "Genetics" below), with the largest contribution coming from variants in the HLA system. But it is important to keep in mind that even with the highest-risk haplotypes, most carriers will *not* develop T1DM. Even in monozygotic twins, the concordance is 30-65%. The observed rise in incidence of T1DM within an essentially genetically stable patient population implies that something has accordingly changed in the environment or the way children are raised. A number of factors, including prenatal influences, diet in infancy, viral infections, lack of exposure to certain infections, even psychologic stress, are implicated in the pathogenesis of T1DM, but their exact role and the mechanism by which they trigger or aggravate autoimmunity remains uncertain (Fig. 589-4). What is clear is that markers of autoimmunity are much more prevalent than clinical T1DM, indicating that initiation of autoimmunity is a necessary but not a sufficient condition for T1DM. Whatever the triggering factor, it seems that in most cases of T1DM that are diagnosed in childhood, the onset of autoimmunity occurs very early in life. In a majority of the children diagnosed before age 10 yr, the first signs of autoimmunity appear before age 2 yr. Development of autoimmunity is associated with the appearance of several

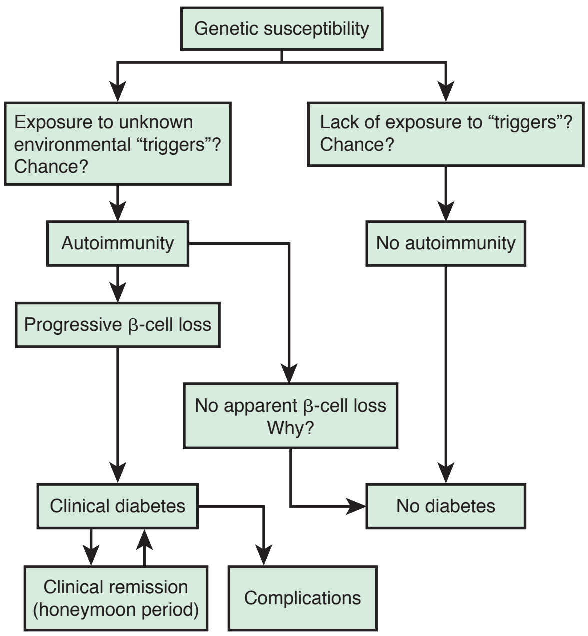

Figure 589-4 **Schematic of the natural history of type 1 diabetes mellitus.** Unknown triggers act upon a genetically susceptible host to trigger autoimmunity. Some proportion of those with autoimmunity develop progressive β-cell loss that eventually leads to clinical diabetes. This is followed by temporary clinical remission (honeymoon period) in most patients. Over time, insulin secretion is almost completely lost and complications may develop in some patients (in direct proportion to the occurrence of hyperglycemia).

autoantibodies. IAAs are usually the first to appear in young children, followed by glutamic acid decarboxylase 65 kDa, and later by tyrosine phosphatase insulinoma–associated 2 and zinc transporter 8 antibodies. The earliest antibodies are predominantly of the IgG_1 subclass. Not only is there "spreading" of autoimmunity to more antigens (IAA, and

then glutamic acid decarboxylase 65 and insulinoma-associated 2 and zinc transporter 8) but there is also epitope spreading within 1 antigen. Initial glutamic acid decarboxylase 65 antibodies tend to be against the middle region or the carboxyl-terminal region, whereas aminoterminal antibodies usually appear later and are less common in children.

Preclinical Autoimmunity with Progressive Loss of β-Cell Function

In some, but not all, patients, the appearance of autoimmunity is followed by progressive destruction of β cells. Antibodies are a marker for the presence of autoimmunity, but the actual damage to the β cells is primarily T-cell mediated (Fig. 589-5). Histologic analysis of the pancreas from patients with recent-onset T1DM reveals insulitis, with an infiltration of the islets of Langerhans by mononuclear cells, including T and B lymphocytes, monocytes/macrophages, and natural killer cells. In the nonobese diabetic mouse, a similar cellular infiltrate is followed by linear loss of β cells until they completely disappear. But it appears that the process in human T1DM is not necessarily linear and there may be an undulating downhill course, with remissions and relapses, in the development of T1DM.

Role of Autoantibodies

Even though T1DM does not occur as a direct consequence of autoantibody formation, the risk of developing clinical disease increases dramatically with an increase in the number of antibodies; only 30% of children with 1 antibody will progress to diabetes, but this risk increases to 70% when 2 antibodies are present and 90% when 3 are present. The risk of progression also varies with the intensity of the antibody response and those with higher antibody titers are more likely to progress to clinical disease. Another factor that appears to influence progression of β-cell damage is the age at which autoimmunity develops; children in whom IAAs appeared within the 1st 2 yr of life rapidly developed anti–islet cell antibodies and progressed to diabetes more frequently than children in whom the first antibodies appeared between ages 5 and 8 yr.

Role of Genetics in Disease Progression

Genetics plays a role in progression to clinical disease. In a large study of healthy children, the appearance of single antibodies is relatively common and usually transient, and does not correlate with the presence of high-risk HLA alleles, but those carrying high-risk HLA alleles are more likely to develop multiple antibodies and progress to disease. Similarly, the appearance of antibodies is more likely to predict diabetes in those with a family history of diabetes vs those with no family history of T1DM. Thus, it may be the case that environmental factors can induce transient autoimmunity in many children, but those with genetic susceptibility are more likely to see progression of autoimmunity and eventual development of diabetes.

Role of Environmental Factors

In addition to genetic factors, environmental factors may also act as accelerators of T1DM after the initial appearance of autoimmunity. This is evident from the fact that the incidence of T1DM can vary several-fold between populations that have the same prevalence of autoimmunity. For instance, the incidence of T1DM in Finland is almost 4-fold higher than in Lithuania, but the incidence of autoimmunity is similar in both countries.

The fact that all children with evidence of autoimmunity and of autoreactive T cells do not progress to diabetes indicates that there are "checkpoints" at which the autoimmune process can be halted or

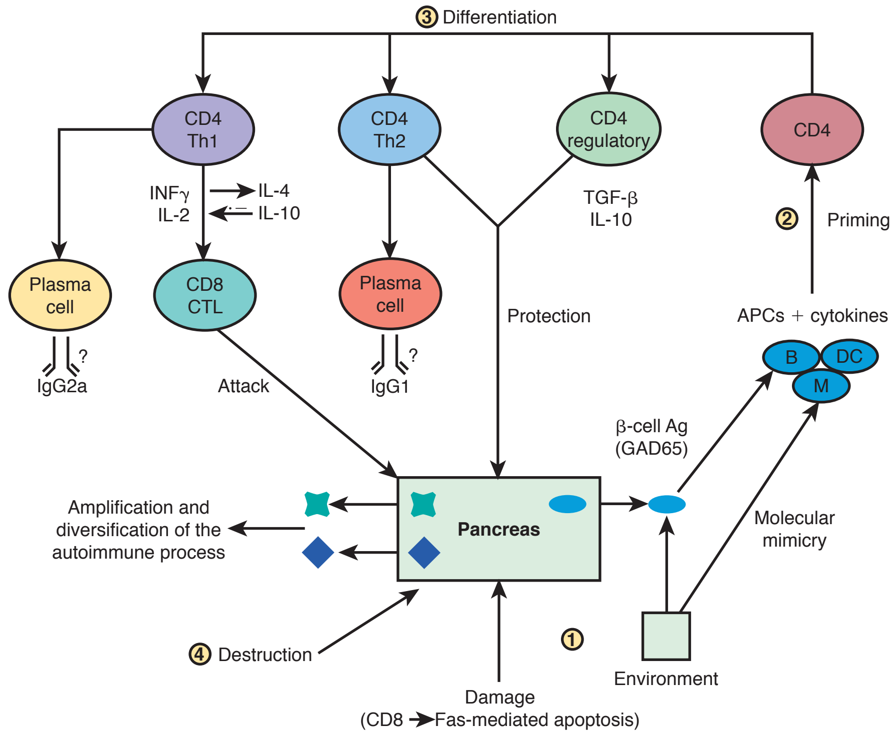

Figure 589-5 **Schematic of the autoimmune response against pancreatic β cells.** An insult to the pancreas leads to the release of β-cell antigens (GAD65), which are taken up by antigen-presenting cells (APCs) and the epitopes presented to the CD4 T cells. Type and stage of activation of APCs as well as the cytokine environment, in which the CD4 T-cell priming takes place, dictate the differentiation of autoreactive T cells toward diabetogenic T-helper type 1 (Th1) cells, T-helper type 2 (Th2) cells, or antigen-specific regulatory T cells. A predominant Th1 autoimmune response results in the recruitment and differentiation of cytotoxic CD8 cells, which attack the pancreatic β cells, leading to a massive release of β-cell antigens (Ag), epitope spreading, and destruction of the pancreatic islets. B, B lymphocyte; CTL, cytotoxic cell; DC, dendritic cell; IL, interleukin; INFγ, interferon-γ; M, macrophage; TGF-β, tumor growth factor β. *(Adapted from Casares S, Brumeanu TD: Insights into the pathogenesis of T1DM: a hint for novel immunospecific therapies,* Curr Mol Med *1:357–378, 2001.)*

reversed before it progresses to full-blown diabetes. This has raised the possibility of preventing T1DM by intervening in the preclinical stage.

Onset of Clinical Disease

Patients with progressive β-cell destruction will eventually present with clinical T1DM. It was thought that 90% of the total β-cell mass is destroyed by the time clinical disease develops, but later studies have revealed that this is not always the case. It now appears that β-cell destruction is more rapid and more complete in younger children, while in older children and adults the proportion of surviving β cells is greater (10-20% in autopsy specimens) and some β cells (about 1% of the normal mass) survive up to 30 yr after the onset of diabetes. As autopsies are usually done on patients who died of diabetic ketoacidosis, these figures may underestimate the actual β-cell mass present at diagnosis. Functional studies indicate that up to 40% of the insulin secretory capacity may be preserved in adults at the time of presentation of T1DM. Ultrasensitive assays indicate that C-peptide production is measurable decades after onset of T1DM. The fact that newly diagnosed diabetic individuals may still have a significant surviving β-cell mass is important because it raises the possibility of secondary prevention of T1DM. Similarly, the existence of viable β cells years or decades after initial presentation indicates that even patients with long-standing diabetes may be able to exhibit some recovery of β-cell function if the autoimmune destructive process can be halted and islet cell regeneration occurs.

PREDICTION AND PREVENTION

Autoimmunity precedes clinical T1DM, and indicators of maturing autoimmune responses may be useful markers for disease prediction. Individuals at risk for T1DM can be identified by a combination of genetic, immunologic, and metabolic markers. The most informative genetic locus, HLA class II, confers about half of the total genetic risk but has a low positive predictive value (PPV) when used in the general population. Autoantibodies provide a practical readout of β-cell autoimmunity, are easily sampled in venous blood, and have become the mainstay of T1DM prediction efforts. In the 1st-degree relatives of patients with T1DM, the number of positive autoantibodies can help estimate the risk of developing T1DM: low risk (single autoantibodies: PPV of 2-6%), moderate risk (2 autoantibodies: PPV of 21-40%), and high risk (>2 autoantibodies: PPV of 59-80%) over a 5 yr period. In children carrying the T1DM highest-risk genotype (HLA-DQB1*0201-DQA1*05/DQB1*0302-DQA1*03), insulitis is almost 10 times more frequent (PPV 21%) than in children with other genotypes (PPV 2.2%). But while autoantibodies are useful for the prediction of T1DM in the relatives of patients with T1DM, outside of that obvious population, the screening of the general population would be required in order to identify healthy subjects at risk of T1DM. Indeed, close to 9 of 10 individuals with new-onset T1DM have no family background of T1DM. This has been difficult, in part, because the observed autoantibody prevalence greatly exceeds the low disease prevalence in nonrelatives, leading to high false-positive rates.

Primary Prevention of Type 1 Diabetes Mellitus

A safe, effective, inexpensive, and easily administered intervention could theoretically be targeted at all newborns, but no such universally effective intervention is yet available. Delaying the introduction of cow's milk protein, delaying introduction of cereals, and increasing the duration of breastfeeding are all potentially beneficial but of unproven value.

In high-risk populations (relatives of individuals with T1DM, especially those with high-risk genotypes), it is feasible to test more targeted interventions. Parenteral insulin and nasal insulin proved similarly ineffective in preventing diabetes, but oral insulin appeared to delay the incidence of diabetes in only some of autoantibody-positive but still prediabetic patients. In the approach to the newly diagnosed patient with T1DM, antigen-specific immunotherapy trials studying the effect of glutamic acid decarboxylase formulated in aluminum hydroxide, IL-1β inhibition, or intranasal insulin have been negative, and anti-CD3 antibodies have been inconclusive.

Secondary Prevention

Immunosuppressants like cyclosporine have been tested after the onset of T1DM, but while they may prolong the honeymoon period, they are associated with significant side effects and are only effective as long as they are being administered, so their use for this purpose has been abandoned.

The possibility of using glucagon-like peptide (GLP)-1 agonists (e.g., exenatide) alone or in combination with immunomodulatory therapies is also being explored as these agents are capable of increasing β-cell mass in animals.

PATHOPHYSIOLOGY

Insulin performs a critical role in the storage and retrieval of cellular fuel. Its secretion in response to feeding is exquisitely modulated by the interplay of neural, hormonal, and substrate-related mechanisms to permit controlled disposition of ingested foodstuff as energy for immediate or future use. Insulin levels must be lowered to then mobilize stored energy during the fasted state. Thus, in normal metabolism, there are regular swings between the postprandial, high-insulin anabolic state and the fasted, low-insulin catabolic state that affect liver, muscle, and adipose tissue (Table 589-3). T1DM is a progressive low-insulin catabolic state in which feeding does not reverse, but rather exaggerates, these catabolic processes. With moderate insulinopenia, glucose utilization by muscle and fat decreases and postprandial hyperglycemia appears. At even lower insulin levels, the liver produces excessive glucose via glycogenolysis and gluconeogenesis, and fasting hyperglycemia begins. Hyperglycemia produces an osmotic diuresis (glycosuria) when the renal threshold is exceeded (180 mg/dL; 10 mmol/L). The resulting loss of calories and electrolytes, as well as the worsening dehydration, produces a physiologic stress with hypersecretion of stress hormones (epinephrine, cortisol, growth hormone, and glucagon). These hormones, in turn, contribute to the metabolic decompensation by further impairing insulin secretion (epinephrine), by antagonizing its action (epinephrine, cortisol, growth hormone), and by promoting glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis (glucagon, epinephrine, growth hormone, and cortisol) while decreasing glucose utilization and glucose clearance (epinephrine, growth hormone, cortisol).

Table 589-3 Influence of Feeding (High Insulin) or of Fasting (Low Insulin) on Some Metabolic Processes in Liver, Muscle, and Adipose Tissue*

	HIGH PLASMA INSULIN (POSTPRANDIAL STATE)	LOW PLASMA INSULIN (FASTED STATE)
Liver	Glucose uptake Glycogen synthesis Absence of gluconeogenesis Lipogenesis Absence of ketogenesis	Glucose production Glycogenolysis Gluconeogenesis Absence of lipogenesis Ketogenesis
Muscle	Glucose uptake Glucose oxidation Glycogen synthesis Protein synthesis	Absence of glucose uptake Fatty acid and ketone oxidation Glycogenolysis Proteolysis and amino acid release
Adipose tissue	Glucose uptake Lipid synthesis Triglyceride uptake	Absence of glucose uptake Lipolysis and fatty acid release Absence of triglyceride uptake

*Insulin is considered to be the major factor governing these metabolic processes. Diabetes mellitus may be viewed as a permanent low-insulin state that, untreated, results in exaggerated fasting.

The combination of insulin deficiency and elevated plasma values of the counterregulatory hormones is also responsible for accelerated lipolysis and impaired lipid synthesis, with resulting increased plasma concentrations of total lipids, cholesterol, triglycerides, and free fatty acids. The hormonal interplay of insulin deficiency and glucagon excess shunts the free fatty acids into ketone body formation; the rate of formation of these ketone bodies, principally β-hydroxybutyrate and acetoacetate, exceeds the capacity for peripheral utilization and renal excretion. Accumulation of these keto acids results in metabolic acidosis (diabetic ketoacidosis [DKA]) and compensatory rapid deep breathing in an attempt to excrete excess CO_2 (Kussmaul respiration). Acetone, formed by nonenzymatic conversion of acetoacetate, is responsible for the characteristic fruity odor of the breath. Ketones are excreted in the urine in association with cations and thus further increase losses of water and electrolyte and bicarbonate regenerating ability. With progressive dehydration, acidosis, hyperosmolality, and diminished cerebral oxygen utilization, consciousness becomes impaired, and the patient ultimately becomes comatose.

CLINICAL MANIFESTATIONS

In diabetes the decreasing β-cell mass with worsening insulinopenia, progressive hyperglycemia, and eventual ketoacidosis all imply that symptoms steadily increase, from early intermittent polyuria to DKA and coma, over weeks usually, rather than months. Initially, when only insulin reserve is limited, occasional postprandial hyperglycemia occurs. When the serum glucose increases above the renal threshold, intermittent polyuria or nocturia begins. With further β-cell loss, chronic hyperglycemia causes a more persistent diuresis, often with nocturnal enuresis, and polydipsia becomes more apparent. Female patients may develop monilial vaginitis from the chronic glycosuria. Calories are lost in the urine (glycosuria), triggering a compensatory hyperphagia. If this hyperphagia does not keep pace with the glycosuria, loss of body fat ensues, with clinical weight loss and diminished subcutaneous fat stores. An average, healthy 10 yr old child consumes approximately 50% of 2,000 daily calories as carbohydrate. As that child becomes diabetic, daily losses of water and glucose may be 5 L and 250 g, respectively, representing 1,000 calories, or 50%, of the average daily caloric intake. Despite the child's compensatory increased intake of food, the body starves because unused calories are lost in the urine.

When extremely low insulin levels are reached, ketoacids accumulate. At this point, the child quickly deteriorates. Ketoacids produce abdominal discomfort or true pain, nausea, and emesis, preventing oral replacement of urinary water losses. Dehydration accelerates, causing weakness or orthostasis—but polyuria persists. As in any hyperosmotic state, the degree of dehydration may be clinically underestimated because intravascular volume is conserved at the expense of intracellular volume. Ketoacidosis exacerbates prior symptoms and leads to Kussmaul respirations (deep, heavy, nonlabored rapid breathing), fruity breath odor (acetone), prolonged corrected Q-T interval, diminished neurocognitive function, and possible coma. Approximately 20-40% of children with new-onset diabetes progress to DKA before diagnosis.

This entire progression happens much more quickly (over a few weeks) in younger children, owing to either more aggressive autoimmune destruction of β cells and/or to lower β-cell mass compared to older subjects. In infants, most of the weight loss is acute water loss because they will not have had prolonged urinary loss of calories from glycosuria, and there will be an increased incidence of DKA at diagnosis. In adolescents, the course is usually more prolonged (over a few months), and most of the weight loss represents fat loss from prolonged starvation. Additional weight loss from acute dehydration may occur just before diagnosis. In any child, the progression of symptoms may be accelerated by the stress of an intercurrent illness or trauma, when counterregulatory (stress) hormones overwhelm the limited insulin secretory capacity.

DIAGNOSIS

The diagnosis of T1DM is usually straightforward (see Table 589-2). Although most symptoms are nonspecific, the most important clue is an inappropriate polyuria in any child with dehydration, poor weight gain, or "the flu." Hyperglycemia, glycosuria, and ketonuria can be determined quickly. Nonfasting blood glucose greater than 200 mg/dL (11.1 mmol/L) with typical symptoms is diagnostic with or without ketonuria. In the obese child, T2DM must be considered (see "Type 2 Diabetes Mellitus" below). Once hyperglycemia is confirmed, it is prudent to determine whether DKA is present (especially if ketonuria is found) and to evaluate electrolyte abnormalities—even if signs of dehydration are minimal. A baseline hemoglobin A_{1c} (HbA_{1c}) will be confirmatory and allows an estimate of the duration of hyperglycemia and provides an initial value by which to compare the effectiveness of subsequent therapy. Falsely low HbA_{1c} levels are noted in hemolytic anemias, pure red cell aplasia, blood transfusions, and anemias associated with hemorrhage, cirrhosis, myelodysplasias, or renal disease treated with erythropoietin.

In the nonobese child, testing for autoimmunity to β cells is not commonly necessary. Other autoimmunities associated with T1DM should be sought, including celiac disease (by tissue transglutaminase IgA and total IgA) and thyroiditis (by antithyroid peroxidase and antithyroglobulin antibodies). Fifteen to 30% of subjects with T1DM have elevated thyroid-stimulating hormone (TSH) and antithyroid antibodies and close to 5-10% have evidence for celiac disease. These diseases share common genes and likely the same interplay between environmental and immunologic factors. Because significant physiologic distress can disrupt the pituitary–thyroid axis, free thyroxine and TSH levels should be checked after the child is stable for a few weeks.

Rarely, a child has transient hyperglycemia with glycosuria while under substantial physical stress. This usually resolves permanently during recovery from the stressors. Stress-produced hyperglycemia can reflect a limited insulin reserve temporarily revealed by counterregulatory hormones. A child with temporary hyperglycemia should therefore be monitored for the development of symptoms of persistent hyperglycemia and tested if such symptoms occur. Formal testing in a child who remains clinically asymptomatic is not necessary; if there is concern for T1DM or T2DM a hemoglobin A_{1c} may be of value.

Routine screening procedures, such as postprandial determinations of blood glucose or screening oral glucose tolerance tests have yielded low detection rates in healthy, asymptomatic children, even among those considered at risk, such as siblings of diabetic children. Accordingly, such screening procedures are not recommended in children.

Diabetic Ketoacidosis

DKA is the end result of the metabolic abnormalities resulting from a severe deficiency of insulin or insulin effectiveness. The latter occurs during stress as counterregulatory hormones block insulin action. DKA occurs in 20-40% of children with new-onset diabetes and in children with known diabetes who omit insulin doses or who do not successfully manage an intercurrent illness. DKA may be arbitrarily classified as mild, moderate, or severe (Table 589-4), and the range of symptoms depends on the depth of ketoacidosis. There is a large amount of ketonuria, an increased ion gap, a decreased serum bicarbonate (or total CO_2) and pH, and an elevated effective serum osmolality, indicating hypertonic dehydration.

TREATMENT

Therapy is tailored to the degree of insulinopenia at presentation. Most children with new diabetes have mild to moderate symptoms, have minimal dehydration with no history of emesis, and have not progressed to ketoacidosis. Once DKA has resolved in the newly diagnosed child, therapy is transitioned to that described for children with nonketotic onset. Children with previously diagnosed diabetes who develop DKA are usually transitioned to their previous insulin regimen.

NEW-ONSET DIABETES WITHOUT KETOACIDOSIS

Excellent diabetes control involves many goals: to maintain a balance between tight glucose control and avoiding hypoglycemia, to eliminate polyuria and nocturia, to prevent ketoacidosis, and to permit normal growth and development with minimal effect on lifestyle. Therapy

Table 589-4 Classification of Diabetic Ketoacidosis

	NORMAL	MILD	MODERATE	SEVERE*
CO_2 (mEq/L, venous)[†]	20-28	16-20	10-15	<10
pH (venous)[†]	7.35-7.45	7.25-7.35	7.15-7.25	<7.15
Clinical	No change	Oriented, alert but fatigued	Kussmaul respirations; oriented but sleepy; arousable	Kussmaul or depressed respirations; sleepy to depressed sensorium to coma

*Severe hypernatremia (corrected Na >150 mEq/L) would also be classified as severe diabetic ketoacidosis.
[†]CO_2 and pH measurement are method dependent; normal ranges may vary.

Table 589-5 Starting Doses of Insulin (units/kg/day)

	NO DIABETIC KETOACIDOSIS	DIABETIC KETOACIDOSIS
Prepubertal	0.25-0.50	0.75-1.0
Pubertal	0.50-0.75	1.0-1.2
Postpubertal	0.25-0.50	0.8-1.0

encompasses initiation and adjustment of insulin, extensive teaching of the child and caretakers, and reestablishment of the life routines. Each aspect should be addressed early in the overall care.

Insulin Therapy

Several factors influence the initial daily insulin dose per kilogram of body weight. The dose is usually higher in pubertal children. It is also higher in those who are in DKA at the time of presentation. Table 589-5 shows the recommended starting total daily dose (units/kg/day) of insulin in children.

The optimal insulin dose can only be determined empirically, with frequent self-monitored blood glucose levels and insulin adjustment by the diabetes team. Many children with new-onset diabetes have some residual β-cell function (the honeymoon period), which is associated with reduced exogenous insulin needs shortly after starting on treatment. Residual β-cell function usually fades within a few months and is reflected as a steady increase in insulin requirements and wider glucose excursions.

The initial insulin schedule should be directed toward the optimal degree of glucose control in an attempt to duplicate the activity of the β cell. There are inherent limits to our ability to mimic the β cell. Exogenous insulin does not have a first pass to the liver, whereas 50% of pancreatic portal insulin is taken up by the liver, a key organ for the disposal of glucose; absorption of an exogenous dose continues despite hypoglycemia, whereas endogenous insulin release ceases and serum levels quickly lower with a normally rapid clearance. The absorption rate from an injection varies by injection site and patient activity level, whereas endogenous insulin is secreted directly into the portal circulation. Despite these fundamental physiologic differences, acceptable glucose control can be obtained with insulin analogs used in a basal-bolus regimen, that is, with slow-onset, long-duration background insulin for between-meal glucose control and rapid-onset insulin at each meal.

All preanalog insulins form hexamers, which must dissociate into monomers subcutaneously before being absorbed into the circulation. Thus, a detectable effect for **regular insulin** is delayed by 30-60 min after injection. This, in turn, requires delaying the meal 30-60 min after the injection for optimal effect—a delay rarely attained in a busy child's life. Regular insulin has a wide peak and a long tail for bolus insulin (Figs. 589-6 and 589-7). This profile limits postprandial glucose control, produces prolonged peaks with excessive hypoglycemic effects between meals, and increases the risk of nighttime hypoglycemia. These unwanted between-meal effects often necessitate "feeding the insulin" with snacks and limiting the overall degree of blood glucose control. **Neutral protamine Hagedorn (NPH) and Lente insulins** also have inherent limits because they do not create a peakless background insulin level (see Fig. 589-7*C-E*). This produces a significant hypoglycemic effect during the midrange of their duration. Thus, it is often difficult to predict their interaction with fast-acting insulins. When regular insulin is combined with NPH or Lente (see Fig. 589-7*E*), the composite insulin profile poorly mimics normal endogenous insulin secretion. Lente and Ultralente insulins have been discontinued and are no longer available.

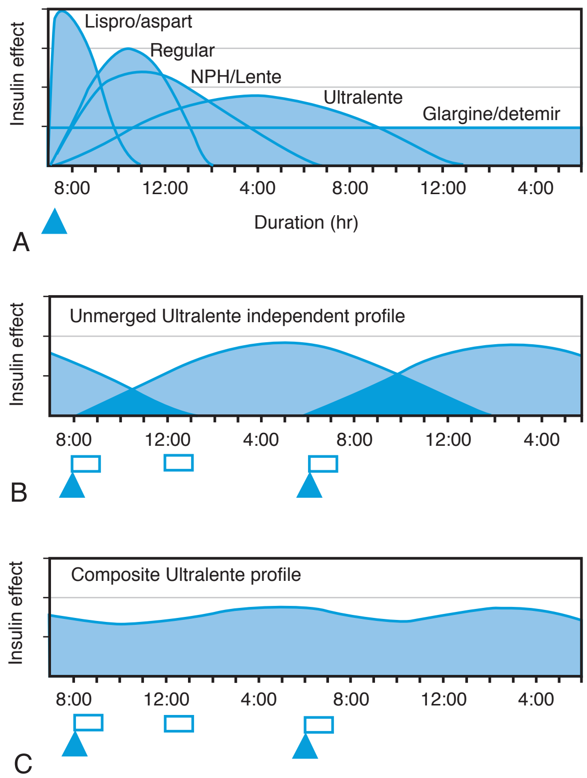

Figure 589-6 Approximate insulin effect profiles. Meals are shown as rectangles below time axis. **A,** The following relative peak effect and duration units are used: lispro/aspart, peak 20 for 4 hr; regular, peak 15 for 7 hr; neutral protamine Hagedorn/Lente, peak 12 for 12 hr; Ultralente, peak 9 for 18 hr; glargine, peak 5 for 24 hr. Although Lente and Ultralente are no longer manufactured, they are shown to give historical comparison to newer insulin analogs. ▲, Injection time. **B,** Two Ultralente injections given at breakfast and supper. Note overlap of profiles. **C,** Composite curve showing approximate cumulative insulin effect for the 2 Ultralente injections. This composite view is much more useful to the patient, parents, and medical personnel because it shows important combined effects of multiple insulin injections with variable absorption characteristics and overlapping durations.

Lispro and aspart, insulin analogs, are absorbed much quicker because they do not form hexamers. They provide discrete pulses with little if any overlap and short tail effect. This allows better control of postmeal glucose increase and reduces between-meal or nighttime

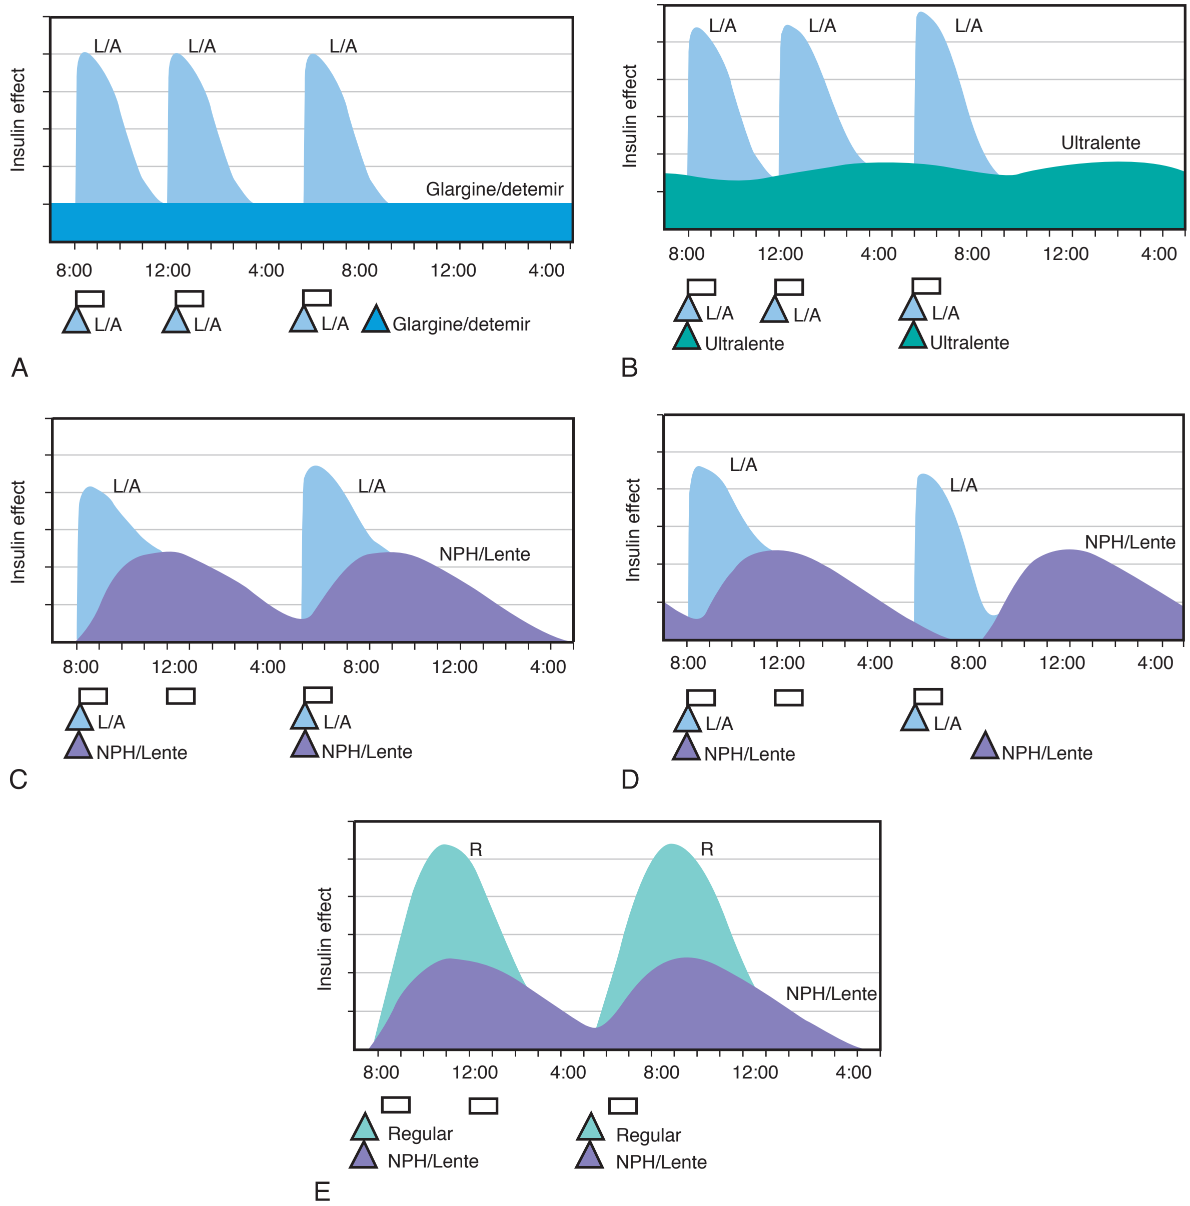

Figure 589-7 **Approximate composite insulin effect profiles.** Meals are shown as rectangles below time axis. Injections are shown as labeled *triangles; L/A,* lispro or aspart. Even though the fast- and long-acting insulins are shaded differently to show the addition of 1 insulin effect to another, the profile is changed to show the combined effect. For example, in the breakfast injection in **C,** the quick decline of L/A effect is blunted by the rising neutral protamine Hagedorn (NPH)/Lente effect, producing a broad tail, which slowly declines to baseline at supper. All profiles are idealized using average absorption and clearance rates. In typical clinical situations, these profiles vary among patients. A given patient has varying rates of absorption depending on the injection site, physical activity, and other variables. **A,** L or A premeal; glargine at bedtime. The rapid onset and short duration of L or A reduce overlap between premeal injections, and there is no extended nighttime action. This reduces the risk of hypoglycemia. Glargine provides a steady basal profile that simplifies prediction of bolus insulin effect. **B,** L or A premeal; Ultralente at breakfast and supper. Ultralente produces a basal profile similar to that seen with glargine. Some excessive insulin effect, however, is seen before supper and at nighttime. **C,** L or A premeal; NPH or Lente at breakfast and supper. The broad peak of NPH or Lente produces substantial risk of hypoglycemia before lunch and during the early hours of the night. The waning insulin effect before supper and breakfast may also allow breakthrough hyperglycemia. **D,** L or A premeal; NPH or Lente at breakfast and bedtime. Moving the evening long-acting insulin helps to cover the prebreakfast hours, but the risk of nighttime lows persists. **E,** Regular and NPH or Lente at breakfast and supper. This produces the least physiologic profile, with large excesses before lunch and during the early night, combined with poor coverage before supper and breakfast. Although Lente and Ultralente are no longer manufactured, they are shown to give historical comparison to newer insulin analogs.

hypoglycemia (see Fig. 589-7*A*). The **long-acting analog glargine** creates a much flatter 24 hr profile, making it easier to predict the combined effect of a rapid bolus (lispro or aspart) on top of the basal insulin, producing a more physiologic pattern of insulin effect (see Fig. 589-7*A*). Postprandial glucose elevations are better controlled, and between-meal and nighttime hypoglycemia are reduced.

Glargine may be given every 12 hr in young children if a single daily dose of glargine does not produce complete 24 hr basal coverage. The basal insulin glargine should be 25-30% of the total dose in toddlers and 40-50% in older children. The remaining portion of the total daily dose is provided as bolus insulin that is dosed by both the carbohydrate content of the meal as well as the preprandial glucose value.

Frequent blood glucose monitoring and insulin adjustment are necessary in the 1st weeks as the child returns to routine activities and adapts to a new nutritional schedule, and as the total daily insulin requirements are determined. The major physiologic limit to tight control is hypoglycemia. Use of insulin analogs moderates but does not eliminate this problem.

Some families may be unable to administer 4 daily injections. In these cases, a compromise may be needed. A 3 injection regimen combining NPH with a rapid analog bolus at breakfast, a rapid-acting analog bolus at supper, and glargine at bedtime may provide fair glucose control. Further compromise to a 2 injection regimen may occasionally be needed and frequently involves use of premix insulin (e.g., 70/30).

Insulin Pump Therapy

Continuous subcutaneous insulin infusion (CSII) via battery-powered pumps provides a closer approximation of normal plasma insulin profiles and increased flexibility regarding timing of meals and snacks compared with conventional insulin injection regimens. Insulin pump models can be programmed with a patient's personal insulin dose algorithms, including the insulin to carbohydrate ratio and the correction scale for premeal glucose levels. The patient can enter the patient's blood glucose level and the carbohydrate content of the meal, and the pump computer will calculate the proper insulin bolus dose. Although CSII frequently improves metabolic control, this may not always be the case. The degree of glycemic control is mainly dependent on how closely patients adhere to the principles of diabetes self-care, regardless of the type of intensive insulin regimen. One benefit of pump therapy may be a reduction in severe hypoglycemia and associated seizures. Randomized trials comparing multiple daily insulin regimens using glargine insulin and CSII in children with T1DM demonstrate similar metabolic control and frequency of hypoglycemic events.

Continuous Glucose Monitoring Systems

Subcutaneous glucose sensors that continuously measure interstitial fluid glucose levels are available and approved for use in children. The 1st generation of continuous glucose monitors provided blood glucose data only after downloading by the physician, and did not provide real-time feedback to the patient. This type of device did not appear to improve glycemic control in children, although there was some educational value in detecting patterns of blood glucose fluctuations and episodes of hypoglycemia during periods of sleep.

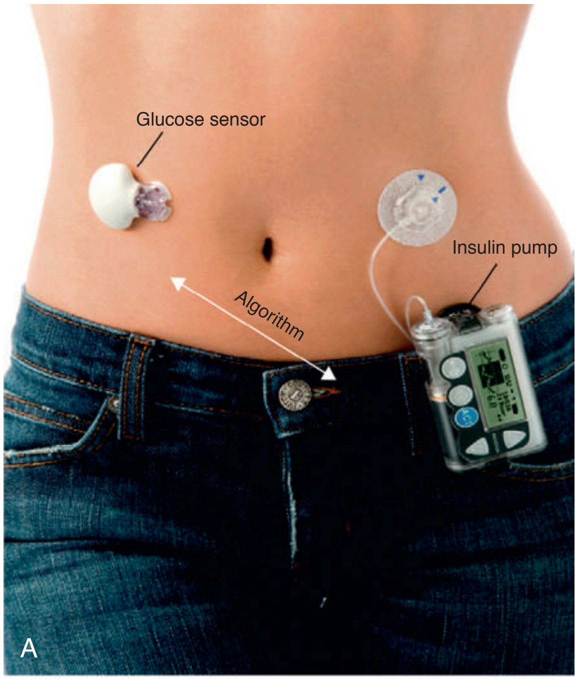
The newer generation of continuous monitors report blood glucose levels to the patient in real time. Short-term studies indicate clinical benefits of these devices as compared to conventional methods of blood glucose monitoring, when used by motivated and well-informed patients. These devices do not directly control insulin administration but provide glucose readings to permit finer control of insulin administration by patients and families. To avoid hypoglycemia the glucose sensor sounds an alarm; many episodes of hypoglycemia occur at night and unfortunately the parent may sleep through the alarm. Studies are currently evaluating the efficacy of a fully automated closed-loop system of insulin delivery based on continuous glucose sensing, sometimes mistakenly known as an "artificial pancreas" (Fig. 589-8). Some automated glycemic systems employ a bihormonal approach (insulin, glucagon) or have an automated insulin suspension program to ensure normal glycemia while avoiding hypoglycemia. The latter hypoglycemia threshold insulin suspension feature greatly reduces the incidence of hypoglycemia, especially at night. The FDA has approved an insulin pump in combination with a continuous glucose monitoring system that will stop insulin delivery when interstitial glucose levels fall below a predetermined level.

Amylin-Based Adjunct Therapy

Pramlintide acetate, a synthetic analog of amylin, may be of therapeutic value combined with insulin therapy. In adolescents it has been shown to decrease postprandial hyperglycemia, insulin dosage, gastric emptying, and HbA_{1c} levels. It is given as a subcutaneous dose before meals.

Basic and Advanced Diabetes Education

Therapy consists not only of initiation and adjustment of insulin dose but also of education of the patient and family. Teaching is most efficiently provided by experienced diabetes educators and nutritionists.



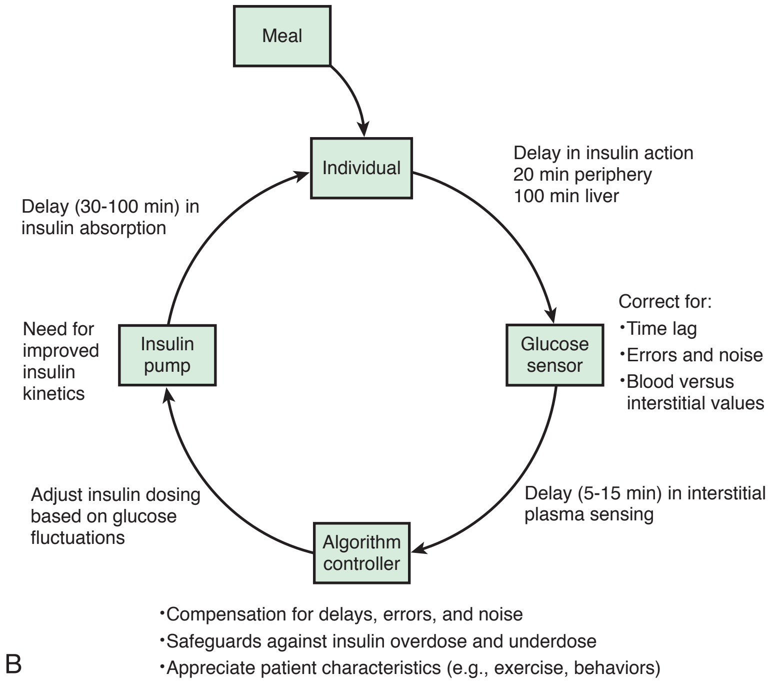


Figure 589-8 Closed-loop system for type 1 diabetes (artificial pancreas). **A,** Prototype of a closed-loop system. **B,** Components of a closed-loop system. Three potential delays in the system include glucose sensing in interstitial fluid, insulin absorption (depends on use of rapid vs regular insulin), and insulin action in peripheral tissues and liver. *(From Atkinson MA, Eisenbarth GS, Michels AW: Type 1 diabetes.* Lancet *383:69–78, 2014, Fig. 5, p. 75.)*

In the acute phase, the family must learn the "basics," which includes monitoring the child's blood glucose and urine and/or blood ketones, preparing and injecting the correct insulin dose subcutaneously at the proper time, recognizing and treating low blood glucose reactions, and having a basic meal plan. Most families are trying to adjust psychologically to the new diagnosis of diabetes in their child and thus have a limited ability to retain new information. Written materials covering these basic topics help the family during the 1st few days.

Children and their families are also required to complete advanced self-management classes in order to facilitate implementation of flexible insulin management. These educational classes will help patients and their families acquire skills for managing diabetes during athletic activities and sick days.

Ketoacidosis

Severe insulinopenia (or lack of effective insulin action) results in a physiologic cascade of events in 3 general pathways:

1. Excessive glucose production coupled with reduced glucose utilization raises serum glucose. This produces an osmotic diuresis, with loss of fluid and electrolytes, dehydration, and activation of the renin–angiotensin–aldosterone axis with accelerated potassium loss. If glucose elevation and dehydration are severe and persist for several hours, the risk of cerebral edema increases.
2. Increased catabolic processes result in cellular losses of sodium, potassium, and phosphate.
3. Increased release of free fatty acids from peripheral fat stores supplies substrate for hepatic ketoacid production. When ketoacids accumulate, buffer systems are depleted and a metabolic acidosis ensues. Therapy must address both the initiating event in this cascade (insulinopenia) and the subsequent physiologic disruptions.

Reversal of DKA is associated with inherent risks that include hypoglycemia, hypokalemia, and cerebral edema. Any protocol must be used with caution and close monitoring of the patient. Adjustments based on sound medical judgment may be necessary for any given level of DKA (Table 589-6).

Hyperglycemia and Dehydration

Insulin must be given at the beginning of therapy to accelerate movement of glucose into cells, to subdue hepatic glucose production, and to halt the movement of fatty acids from the periphery to the liver. An initial insulin bolus does not speed recovery and may increase the risk of hypokalemia and hypoglycemia. Therefore, insulin infusion is typically begun **without** a bolus at a rate of 0.1 units/kg/hr. This approximates maximal insulin output in normal subjects during an oral glucose tolerance test. Rehydration also lowers glucose levels by improving renal perfusion and enhancing renal excretion. The combination of these therapies usually causes a rapid initial decline in serum glucose levels. Once glucose goes below 180 mg/dL (10 mmol/L), the osmotic diuresis stops and rehydration accelerates without further increase in the infusion rate.

Repair of hyperglycemia occurs well before correction of acidosis. Therefore, insulin is still needed to control fatty acid release and ketosis after normal glucose levels are reached. To continue the insulin infusion without causing hypoglycemia, glucose must be added to the infusion. We typically recommend that glucose be added as a 5% solution when the serum glucose has decreased <300 mg/dL and as a 10% solution when the serum glucose has decreased <200 mg/dL. The insulin infusion can also be lowered from the initial maximal rate if, despite the above outlined interventions, the serum glucose falls further.

Repair of fluid deficits must be tempered by the potential risk of cerebral edema. It is prudent to approach any child in any hyperosmotic state with cautious rehydration. The effective serum osmolality ($E_{osm} = 2 \times [Na_{uncorrected}] + [glucose]$) is an accurate index of tonicity of the body fluids, reflecting intracellular and extracellular hydration better than measured plasma osmolality. It is calculated with sodium and glucose in mmol/L. This value is usually elevated at the beginning of therapy and should steadily normalize. A rapid decline, or a slow decline to a subnormal range, may indicate an excess of free water entering the vascular space and an increasing risk of cerebral edema. Therefore, patients should not be allowed oral fluids until rehydration is well underway and significant electrolyte shifts are no longer likely. Limited ice chips may be given as a minimal oral intake. All fluid intake and output should be closely monitored.

Calculation of fluid deficits using clinical signs is difficult in children with DKA because intravascular volume is better maintained in the hypertonic state. For any degree of tachycardia, delayed capillary refill, decreased skin temperature, or orthostatic blood pressure change, the child with DKA will be more dehydrated than the child with a normotonic fluid deficit. The protocol in Table 589-6 corrects a deficit of 85 mL/kg (8.5% dehydration) for all patients in the 1st 24 hr. Children with mild DKA rehydrate earlier and can be switched to oral intake,

Table 589-6 Diabetic Ketoacidosis Treatment Protocol

TIME	THERAPY	COMMENTS
1st hr	10-20 mL/kg IV bolus 0.9% NaCl or LR Insulin drip at 0.05 to 0.10 units/kg/hr	Quick volume expansion; may be repeated. NPO. Monitor I/O, neurologic status. Use flow sheet. Have mannitol at bedside; 1 g/kg IV push for cerebral edema
2nd hr until DKA resolution	0.45% NaCl: plus continue insulin drip 20 mEq/L KPhos and 20 mEq/L KAc 5% glucose if blood sugar >250 mg/dL (14 mmol/L)	$\text{IV rate} = \frac{85\ \text{mL/kg} + \text{maintenance} - \text{bolus}}{23\ \text{hr}}$ If K <3 mEq/L, give 0.5-1.0 mEq/kg as oral K solution *or* increase IV K to 80 mEq/L
Variable	Oral intake with subcutaneous insulin	No emesis; CO_2 ≥16 mEq/L; normal electrolytes
Note that the initial IV bolus is considered part of the total fluid allowed in the 1st 24 hr and is subtracted before calculating the IV rate.		
Maintenance (24 hr) = 100 mL/kg (for the first 10 kg) + 50 mL/kg (for the second 10 kg) + 25 mL/kg (for all remaining kg)		
Sample calculation for a 30-kg child: 1st hr = 300 mL IV bolus 0.9% NaCl or LR $\text{2nd and subsequent hr} = \frac{(85\ \text{mL} \times 30) + 1750\ \text{mL} - 300\ \text{mL}}{23\ \text{hr}} = \frac{175\ \text{mL}}{\text{hr}}$ (0.45% NaCl with 20 mEq/L Kphos and 20 mEq/L KAc)		

DKA, diabetic ketoacidosis; I/O, input and output (urine, emesis); K, potassium; KAc, potassium acetate; KPhos, potassium phosphate; LR, lactated Ringer solution; NaCl, sodium chloride; NPO, nothing by mouth.

whereas those with severe DKA and a greater volume deficit require 30-36 hr with this protocol. This more gradual rehydration of the child with severe DKA is an inherent safety feature. The initial intravenous bolus (20 mL/kg of glucose-free isotonic sodium salt solution such as Ringer lactate or 0.9% sodium chloride) for all patients ensures a quick volume expansion and may be repeated if clinical improvement is not quickly seen. This bolus is given as isotonic saline because the patient is inevitably hypertonic, keeping most of the initial infusion in the intravascular space. Subsequent fluid is hypotonic to repair the free water deficit, to allow intracellular rehydration, and to allow a more appropriate replacement of ongoing hypotonic urine losses.

The initial serum sodium is usually normal or low because of the osmolar dilution of hyperglycemia and the effect of an elevated sodium-free lipid fraction. An estimate of the reconstituted, or "true," serum sodium for any given glucose level above 100 mg/dL (5.6 mmol/L) is calculated as follows:

$[Na^+] + (1.6\ mEq/L\ Na^+$ for every 100 mg/dL glucose in excess of 100)

or

$[Na^+] + (1.6\ mEq/L\ Na^+$ for every 5.6 mmol/L glucose in excess of 5.6)

The sodium should increase by approximately 1.6 mmol/L for each 100 mg/dL decline in the glucose. The corrected sodium is usually normal or slightly elevated and indicates moderate hypernatremic dehydration. If the corrected value is greater than 150 mmol/L, severe hypernatremic dehydration may be present and may require slower fluid replacement. The sodium should steadily increase with therapy. *Declining sodium may indicate excessive free water accumulation and increased risk of cerebral edema.*

Catabolic Losses

Both the metabolic shift to a catabolic predominance and the acidosis move potassium and phosphate from the cell to the serum. The osmotic diuresis, the kaliuretic effect of the hyperaldosteronism, and the ketonuria then accelerate renal losses of potassium and phosphate. Sodium is also lost with the diuresis, but free water losses are greater than isotonic losses. With prolonged illness and severe DKA, total body losses can approach 10-13 mEq/kg of sodium, 5-6 mEq/kg of potassium, and 4-5 mEq/kg of phosphate. These losses continue for several hours during therapy until the catabolic state is reversed and the diuresis is controlled. For example, 50% of infused sodium may be lost in the urine during IV therapy. Even though the sodium deficit may be repaired within 24 hr, intracellular potassium and phosphate may not be completely restored for several days.

Although patients with DKA have a total body potassium deficit, the initial serum level is often normal or elevated. This is caused by the movement of potassium from the intracellular space to the serum, both as part of the ketoacid buffering process and as part of the catabolic shift. These effects are reversed with therapy, and potassium returns to the cell. Improved hydration increases renal blood flow, allowing for increased excretion of potassium in the elevated aldosterone state. The net effect is often a dramatic decline in serum potassium levels, especially in severe DKA, and can precipitate changes in cardiac conductivity, flattening of T waves, and prolongation of the QRS complex and can cause skeletal muscle weakness or ileus. The risk of myocardial dysfunction is increased with shock and acidosis. Potassium levels must be closely followed and electrocardiographic monitoring continued until DKA is substantially resolved. If needed, the parenteral potassium can be increased to 80 mEq/L or an oral supplement can be given if there is no emesis. Rarely, the IV insulin must be temporarily stopped.

It is unclear whether phosphate deficits contribute to symptoms of DKA such as generalized muscle weakness. In pediatric patients, a deficit has not been shown to compromise oxygen delivery via a deficiency of 2,3-diphosphoglycerate. Because the patient will receive an excess of chloride, which may aggravate acidosis, it is prudent to use potassium phosphate rather than potassium chloride as a potassium source. Potassium acetate is also used, because it provides an additional buffer.

Pancreatitis is occasionally seen with DKA, especially if prolonged abdominal distress is present; serum amylase may be elevated. If the serum lipase is not elevated, the amylase is likely nonspecific or salivary in origin. Serum creatinine adjusted for age may be falsely elevated owing to interference by ketones in the autoanalyzer methodology. An initial elevated value rarely indicates renal failure and should be rechecked when the child is less ketonemic. Blood urea nitrogen may be elevated with prerenal azotemia and should be rechecked as the child is rehydrated. Mildly elevated creatine or blood urea nitrogen is not a reason to withhold potassium therapy if good urinary output is present.

Keto Acid Accumulation

Low insulin infusion rates (0.02-0.05 units/kg/hr) are usually sufficient to stop peripheral release of fatty acids, thereby eliminating the flow of substrate for ketogenesis. Therefore, the initial infusion rate may be decreased if blood glucose levels go below 150 mg/dL (8 mmol/L) despite the addition of glucose to the infusion. Ketogenesis continues until fatty acid substrates already in the liver are depleted, but this production declines much more quickly without new substrate inflow. Bicarbonate buffers, regenerated by the distal renal tubule and by metabolism of ketone bodies, steadily repair the acidosis once ketoacid production is controlled. *Bicarbonate therapy is rarely necessary and may even increase the risk of hypokalemia and cerebral edema.*

There should be a steady increase in pH and serum bicarbonate as therapy progresses. Kussmaul respirations should abate and abdominal pain resolve. Persistent acidosis may indicate inadequate insulin or fluid therapy, infection, or rarely lactic acidosis. Urine ketones may be positive long after ketoacidosis has resolved because the nitroprusside reaction routinely used to measure urine ketones by dipstick measures only acetoacetate. During DKA, most excess ketones are β-hydroxybutyrate, which increases the normal ratio to acetoacetate from 3 : 1 to as high as 8 : 1. With resolution of the acidosis, β-hydroxybutyrate converts to acetoacetate, which is excreted into the urine and detected by the dipstick test. Therefore, persistent ketonuria may not accurately reflect the degree of clinical improvement and should not be relied on as an indicator of therapeutic failure.

All patients with DKA should be checked for initiating events that may have triggered the metabolic decompensation.

Diabetic Ketoacidosis Protocol

See Table 589-6.

Even though DKA can be of variable severity, a common approach to all cases simplifies the therapeutic regimen and can be safely used for most children. Fluids are best calculated based on weight, not body surface area (m^2), because heights are rarely available for the acutely critically ill child. A standard water deficit (85 mL/kg) is assumed. This amount, when added to maintenance, yields approximately 4 L/m^2 for children of all sizes. Children with milder DKA recover in 10-20 hr (and need less total IV fluid before switching to oral intake), whereas those with more severe DKA require 30-36 hr with this protocol. Any child can be easily transitioned to oral intake and subcutaneous insulin when DKA has resolved (total CO_2 >15 mEq/L; pH >7.30; sodium stable between 135 and 145 mEq/L; no emesis). The first dose of short-acting subcutaneous insulin is given with a meal, and the insulin drip is discontinued approximately 30 min later.

A flow sheet is mandatory for accurate monitoring of changes in acidosis, electrolytes, fluid balance, and clinical status, especially if the patient is transferred from the emergency department to an inpatient setting with new caretakers. This flow sheet is best implemented by a central computer system, which allows for rapid update and wide availability of results, as well as rule-driven highlighting of critical values. A paper flow sheet suffices if it stays with the patient, is kept current, and is reviewed frequently by the physician. Any flow sheet should include columns for serial electrolytes, pH, glucose, and fluid balance. Blood testing should occur every 1-2 hr for children with severe DKA and every 3-4 hr for those with mild to moderate DKA.

Cerebral Edema

Cerebral edema complicating DKA remains the major cause of morbidity and mortality in children and adolescents with T1DM. However, its etiology remains unknown. A case-control study of DKA suggested that baseline acidosis and abnormalities of sodium, potassium, and blood urea nitrogen concentrations were important predictors of risk of cerebral edema. Early bolus administration of insulin and high volumes of fluid were also identified as risk factors. The incidence of cerebral edema in children with DKA has not changed over the past 15-20 yr, despite the widespread introduction of gradual rehydration protocols during this interval. Radiographic imaging is frequently unhelpful in making the diagnosis of cerebral edema. Consequently, each patient must be closely monitored. For all but the mildest cases, this includes frequent neurologic checks for any signs of increasing intracranial pressure, such as a change of consciousness, depressed respiration, worsening headache, bradycardia, apnea, pupillary changes, papilledema, posturing, and seizures. Mannitol must be readily available for use at the earliest sign of cerebral edema. The physician must also keep informed of the laboratory changes; hypokalemia or hypoglycemia can occur rapidly. Children with moderate to severe DKA have a higher overall risk and should be treated in an intensive care environment.

Nonketotic Hyperosmolar Coma

This syndrome is characterized by severe hyperglycemia (blood glucose >800 mg/dL), absence of or only slight ketosis, nonketotic acidosis, severe dehydration, depressed sensorium or frank coma, and various neurologic signs that may include grand mal seizures, hyperthermia, hemiparesis, and positive Babinski signs. Respirations are usually shallow, but coexistent metabolic (lactic) acidosis may be manifested by Kussmaul breathing. Serum osmolarity is commonly 350 mOsm/kg or greater. This condition is uncommon in children; among adults, mortality rates are high, possibly in part because of delays in recognition and institution of appropriate therapy. In children, there has been a high incidence of preexisting neurologic damage. Profound hyperglycemia may develop over a period of days and, initially, the obligatory osmotic polyuria and dehydration may be partially compensated for by increasing fluid intake. With progression of disease, thirst becomes impaired, possibly because of alteration of the hypothalamic thirst center by hyperosmolarity and, in some instances, because of a preexisting defect in the hypothalamic osmoregulating mechanism.

The low production of ketones is attributed mainly to the hyperosmolarity, which in vitro blunts the lipolytic effect of epinephrine and the antilipolytic effect of residual insulin; blunting of lipolysis by the therapeutic use of β-adrenergic blockers may contribute to the syndrome. Depression of consciousness is closely correlated with the degree of hyperosmolarity in this condition as well as in DKA. Hemoconcentration may also predispose to cerebral arterial and venous thromboses.

Treatment of nonketotic hyperosmolar coma is directed at rapid repletion of the vascular volume deficit and very slow correction of the hyperosmolar state. One-half isotonic saline (0.45% NaCl; some use normal saline) is administered at a rate estimated to replace 50% of the volume deficit in the 1st 12 hr, and the remainder is administered during the ensuing 24 hr. The rate of infusion and the saline concentration are titrated to result in a slow decline of serum osmolality. When the blood glucose concentration approaches 300 mg/dL, the hydrating fluid should be changed to 5% dextrose in 0.2 normal saline. Approximately 20 mEq/L of potassium chloride should be added to each of these fluids to prevent hypokalemia. Serum potassium and plasma glucose concentrations should be monitored at 2 hr intervals for the 1st 12 hr and at 4 hr intervals for the next 24 hr to permit appropriate adjustments of administered potassium and insulin.

Insulin can be given by continuous intravenous infusion beginning with the 2nd hr of fluid therapy. Blood glucose may decrease dramatically with fluid therapy alone. The IV insulin dosage should be 0.05 units/kg/hr rather than 0.1 units/kg/hr as advocated for patients with DKA.

Nutritional Management

Nutrition plays an essential role in the management of patients with T1DM. This is of critical importance during childhood and adolescence, when appropriate energy intake is required to meet the needs for energy expenditure, growth, and pubertal development. There are no special nutritional requirements for the diabetic child other than those for optimal growth and development. In outlining nutritional requirements for the child on the basis of age, sex, weight, and activity, food preferences, including cultural and ethnic ones, must be considered.

Total recommended caloric intake is based on size or surface area and can be obtained from standard tables (Tables 589-7 and 589-8). The caloric mixture should comprise approximately 55% carbohydrate, 30% fat, and 15% protein. Approximately 70% of the carbohydrate content should be derived from complex carbohydrates such as starch; intake of sucrose and highly refined sugars should be limited. Complex carbohydrates require prolonged digestion and absorption so that plasma glucose levels increase slowly, whereas glucose from refined sugars, including carbonated beverages, is rapidly absorbed and may cause wide swings in the metabolic pattern; carbonated beverages should be sugar free. Priority should be given to total calories and total carbohydrate consumed rather than its source. Carbohydrate counting has become a mainstay in the nutrition education and management of patients with DM. Patients and their families are provided with information regarding the carbohydrate contents of different foods and food label reading. This allows patients to adjust their insulin dosage to their mealtime carbohydrate intake. The use of carbohydrate counting and insulin to carbohydrate ratios and the use of fast-acting insulin analogs and long-acting basal insulin (detemir and glargine) provide many children with less rigid meal planning. Flexibility in the use of insulin in relation to carbohydrate content of food improves the quality of life.

Although in children there is concern about the potential cumulative effect of saccharin, available data do not support an association of moderate amounts with bladder cancer. Other nonnutritive sweeteners such as aspartame are used in a variety of products.

Diets with high fiber content are useful in improving control of blood glucose. Moderate amounts of sucrose consumed with fiber-rich foods such as whole-grain bread may have no more glycemic effect than their low-fiber, sugar-free equivalents.

The intake of fat is adjusted so that the polyunsaturated:saturated ratio is increased to approximately 1.2 :1.0, in contrast to the estimated American average of 0.3 :1.0. Dietary fats derived from animal sources are, therefore, reduced and replaced by polyunsaturated fats from vegetable sources. Substituting margarine for butter, vegetable oil for

Table 589-7 Calorie Needs for Children and Young Adults

Table 589-8 Summary of Nutrition Guidelines for Children and/or Adolescents with Type 1 Diabetes Mellitus

NUTRITION CARE PLAN

Promotes optimal compliance.

Incorporates goals of management: normal growth and development, control of blood glucose, maintenance of optimal nutritional status, and prevention of complications. Uses staged approach.

NUTRIENT RECOMMENDATIONS AND DISTRIBUTION

NUTRIENT	(%) OF CALORIES	RECOMMENDED DAILY INTAKE
Carbohydrate	Will vary	High fiber, especially soluble fiber; optimal amount unknown
Fiber	>20 g/day	
Protein	12-20	
Fat	<30	
Saturated	<10	
Polyunsaturated	6-8	
Monounsaturated	Remainder of fat allowance	
Cholesterol		300 mg
Sodium		Avoid excessive; limit to 3,000-4,000 mg if hypertensive

ADDITIONAL RECOMMENDATIONS

Energy: If using measured diet, reevaluate prescribed energy level at least every 3 mo.

Protein: High-protein intakes may contribute to diabetic nephropathy. Low intakes may reverse preclinical nephropathy. Therefore, 12-20% of energy is recommended; lower end of range is preferred. In guiding toward the end of the range, a staged approach is useful.

Alcohol: Safe use of moderate alcohol consumption should be taught as routine anticipatory guidance as early as junior high school.

Snacks: Snacks vary according to individual needs (generally 3 snacks per day for children; midafternoon and bedtime snacks for junior high children or teens).

Alternative sweeteners: Use of a variety of sweeteners is suggested.

Educational techniques: No single technique is superior. Choice of educational method used should be based on patient needs. Knowledge of variety of techniques is important. Follow-up education and support are required.

Eating disorders: Best treatment is prevention. Unexplained poor control or severe hypoglycemia may indicate a potential eating disorder.

Exercise: Education is vital to prevent delayed or immediate hypoglycemia and to prevent worsened hyperglycemia and ketosis.

From Connell JE, Thomas-Doberson D: Nutritional management of children and adolescents with insulin-dependent diabetes mellitus: a review by the Diabetes Care and Education Dietetic Practice Group, J Am Diet Assoc 91:1556, 1991.

animal oils in cooking, and lean cuts of meat, poultry, and fish for fatty meats is advisable. The intake of cholesterol is also reduced by these measures and by limiting the number of egg yolks consumed. These simple measures reduce serum low-density lipoprotein cholesterol, a predisposing factor to atherosclerotic disease. Less than 10% of calories should be derived from saturated fats and up to 10% from polyunsaturated fats; the remaining fat-derived calories should be derived from monounsaturated fats. Table 589-8 summarizes current nutritional guidelines.

Each child/family can and should select a diet based on personal taste with the help of the physician or dietitian (or both). Emphasis should be placed on regularity of food intake and on constancy of carbohydrate intake. Occasional excesses ("treats") for birthdays and other parties are permissible and tolerated to not foster rebellion and stealth in obtaining desired food. Cakes and even candies are permissible on special occasions as long as the food carbohydrate content is adjusted in the meal plan. Adjustments in meal planning must constantly be made to meet the needs as well as the desires of each child. A consistent eating pattern with appropriate supplements for exercise, the pubertal growth spurt, and pregnancy in an adolescent with diabetes is important for metabolic control.

Monitoring

Success in the daily management of the child with diabetes can be measured by the competence acquired by the family, and subsequently by the child, in assuming responsibility for daily self-care. Their initial and ongoing instruction in conjunction with their supervised experience can lead to a sense of confidence in making adjustments in insulin dosage for dietary deviations, for unusual physical activity, and even for some minor intercurrent illnesses. Such acceptance of responsibility should make them relatively independent of the physician for their ordinary care. The physician must maintain ongoing interested supervision and shared responsibility with the family and the child.

Self-monitoring of blood glucose is an essential component of managing diabetes. Monitoring often also needs to include insulin dose, unusual physical activity, dietary changes, hypoglycemia, intercurrent illness, and other items that may influence the blood glucose. These items may be valuable in interpreting the self-monitoring of blood glucose record, prescribing appropriate adjustments in insulin doses, and teaching the family. If there are discrepancies in the self-monitoring of blood glucose and other measures of glycemic control (such as the HbA_{1c}), the clinician should attempt to clarify the situation in a manner that does not undermine their mutual confidence.

Daily blood glucose monitoring has been markedly enhanced by the availability of strips impregnated with glucose oxidase that permit blood glucose measurement from a drop of blood. A portable calibrated reflectance meter can approximate the blood glucose concentration accurately. Many meters contain a memory "chip" enabling recall of each measurement, its average over a given interval, and the ability to display the pattern on a computer screen. Such information is a useful educational tool for verifying degree of control and modifying recommended regimens. A small, spring-loaded device that automates capillary bloodletting (lancing device) in a relatively painless fashion is commercially available. Parents and patients should be taught to use these devices and measure blood glucose at least 4 times daily—before breakfast, lunch, and supper, and at bedtime. When insulin therapy is initiated and when adjustments are made that may affect the overnight glucose levels, self-monitoring of blood glucose should also be performed at 12 midnight and 3 AM to detect nocturnal hypoglycemia. Ideally, the blood glucose concentration should range from approximately 80 mg/dL in the fasting state to 140 mg/dL after meals. In practice, however, a range is acceptable, based on age of the patient (Table 589-9). Blood glucose measurements that are consistently at or outside these limits, in the absence of an identifiable cause such as exercise or dietary indiscretion, are an indication for a change in the insulin dose. If the fasting blood glucose is high, the evening dose of long-acting insulin is increased by 10-15% and/or additional fast-acting insulin (lispro or aspart) coverage for bedtime snack may be considered. If the noon glucose level exceeds set limits, the morning fast-acting insulin (lispro or aspart) is increased by 10-15%. If the presupper glucose is high, the noon dose of fast-acting insulin is increased by 10-15%. If the prebedtime glucose is high, the presupper dose of fast-acting insulin is increased by 10-15%. Similarly, reductions in the insulin type and dose should be made if the corresponding blood glucose measurements are consistently below desirable limits.

A minimum of 4 daily blood glucose measurements should be performed. However, some children and adolescents may need to have more frequent blood glucose monitoring based on their level of physical activity and history of frequent hypoglycemic reactions. Families should be encouraged to become sufficiently knowledgeable about managing diabetes. They can maintain near-normal glycemia for prolonged periods by self-monitoring of blood glucose levels before and

Table 589-9 Target Premeal and 30-Day Average Blood Glucose Ranges and the Corresponding Hemoglobin A_{1c} for Each Age Group

AGE GROUP (yr)	TARGET PREMEAL BG RANGE (mg/dL)	30-DAY AVERAGE BG RANGE (mg/dL)	TARGET HbA_{1c} (%)
<5	100-200	180-250	7.5-9.0
5-11	80-150	150-200	6.5-8.0
12-15	80-130	120-180	6.0-7.5
16-18	70-120	100-150	5.5-7.0

In our laboratory, the nondiabetic reference range for HbA_{1c} is 4.5-5.7% (95% confidence interval).
BG, blood glucose; HbA_{1c}, hemoglobin A_{1c}.

2 hr after meals, and in conjunction with multiple daily injections of insulin, adjusted as necessary.

A continuous glucose monitoring system (CGMS) records data obtained from a subcutaneous sensor every 5 min for up to 72 hr and provides the clinician with a continuous profile of tissue glucose levels. The interstitial glucose levels lag about 13 min behind the blood glucose values at any given level. The CGMS values tend to have a high correlation coefficient for blood glucose values ranging between 40 and 400 mg/dL. CGMS is minimally invasive and entails the placement of a small, subcutaneous catheter that can be easily worn by adults and children. The system provides information that allows the patient and healthcare team to adjust the insulin regimen and the nutrition plan to improve glycemic control. CGMS can be helpful in detecting asymptomatic nocturnal hypoglycemia as well as in lowering HbA_{1c} values without increasing the risk for severe hypoglycemia. Although there are potential pitfalls in CGMS use, including suboptimal compliance, human error, incorrect technique, and sensor failure, the implementation of CGMS in ambulatory diabetes practice allows the clinician to diagnose abnormal glycemic patterns in a more precise manner.

Real-Time Continuous Glucose Monitoring

Real-time continuous glucose monitoring is a technology with the potential of transforming current concepts of glycemic control and optimal diabetes management. In addition to displaying real-time glucose data, newer generations of continuous glucose monitors also have alarms that can be set at below or above predetermined blood glucose thresholds. This safety feature can help parents of young children to recognize nocturnal hypoglycemia. In addition, continuous glucose monitoring shows the rate and direction of glucose change and alerts patients to trends that could lead to dangerous hypoglycemia or hyperglycemia. However, the use of continuous glucose monitoring without clinical decision-making algorithms and guidelines has not been proven to be very effective in improving glycemic control.

Glycosylated Hemoglobin

A reliable index of long-term glycemic control is provided by measurement of glycosylated hemoglobin. HbA_{1c} represents the fraction of hemoglobin to which glucose has been nonenzymatically attached in the bloodstream. The formation of HbA_{1c} is a slow reaction that is dependent on the prevailing concentration of blood glucose; it continues irreversibly throughout the red blood cell's life span of approximately 120 days. The higher the blood glucose concentration and the longer the red blood cell's exposure to it, the higher is the fraction of HbA_{1c}, which is expressed as a percentage of total hemoglobin. Because a blood sample at any given time contains a mixture of red blood cells of varying ages, exposed for varying times to varying blood glucose concentrations, an HbA_{1c} measurement reflects the average blood glucose concentration from the preceding 2-3 mo. When measured by standardized methods to remove labile forms, the fraction of HbA_{1c} is not influenced by an isolated episode of hyperglycemia.

It is recommended that HbA_{1c} measurements be obtained 3-4 times/yr to obtain a profile of long-term glycemic control. The lower the HbA_{1c} level, the more likely it is that microvascular complications such as retinopathy and nephropathy will be less severe, delayed in appearance, or even avoided altogether. Depending on the method used for determination, HbA_{1c} values may be spuriously elevated in thalassemia (or other conditions with elevated hemoglobin F) and spuriously lower in sickle cell disease (or other conditions with high red blood cell turnover). Although values of HbA_{1c} may vary according to the method used for measurement, in individuals without diabetes, the HbA_{1c} fraction is usually less than 6%; in individuals with diabetes, values of 6-7.5% represent good metabolic control, values of 7.6-9.9%, fair control, and values of 10% or higher, poor control. The target HbA_{1c} of <7.5% is the same regardless of the patient's age (see Table 589-9).

Exercise

No form of exercise, including competitive sports, should be forbidden to the child with diabetes. A major complication of exercise in patients with diabetes is the presence of a hypoglycemic reaction during or within hours after exercise. If hypoglycemia does not occur with exercise, adjustments in diet or insulin are not necessary, and glucoregulation is likely to be improved through the increased utilization of glucose by muscles. The major contributing factor to hypoglycemia with exercise is an increased rate of absorption of insulin from its injection site. Higher insulin levels dampen hepatic glucose production so that it is inadequate to meet the increased glucose utilization of exercising muscle. Regular exercise also improves glucoregulation by increasing insulin receptor number. In patients who are in poor metabolic control, vigorous exercise may precipitate ketoacidosis because of the exercise-induced increase in the counterregulatory hormones.

Benefits of Improved Glycemic Control

The Diabetes Control and Complications Trial (DCCT) established conclusively the association between higher glucose levels and long-term microvascular complications. Intensive management produced dramatic reductions of retinopathy, nephropathy, and neuropathy by 47-76%. The data from the adolescent cohort demonstrated the same degree of improvement and the same relationship between the outcome measures of microvascular complications.

The beneficial effect of intensified treatment was determined by the degree of blood glucose normalization, independently of the type of intensified treatment used. Frequent blood glucose monitoring was considered an important factor in achieving better glycemic control for the intensively treated adolescents and adults. Patients who were intensively treated had individualized glucose targets, frequent adjustments based on ongoing capillary blood glucose monitoring, and a team approach that focused on the person with diabetes as the prime initiator of ambulatory care. Care was constantly adjusted toward reaching normal or near-normal glycemic goals while avoiding or minimizing severe episodes of hypoglycemia. Teaching emphasized a preventive approach to blood glucose fluctuations with constant readjustment to counterbalance any high or low blood glucose readings. Target blood glucose goals were adjusted upward if hypoglycemia could not be prevented.

Total duration of diabetes contributes to development and severity of complications. Nonetheless, many professionals have concerns

about applying the results of the DCCT to preschool-age children, who often have hypoglycemia unawareness with unique safety issues, and to prepubertal school-age children, who were not included in the DCCT. When the DCCT ended in 1993, researchers continued to study more than 90% of participants. The follow-up study, called Epidemiology of Diabetes Interventions and Complications (EDIC), was assessing the incidence and predictors of cardiovascular disease events such as heart attack, stroke, or needed heart surgery, as well as diabetic complications related to the eye, kidney, and nerves. The EDIC demonstrated that **intensive blood glucose control reduced risk** of any cardiovascular disease event by 42%. In addition, intensive therapy reduced risk of nonfatal heart attack, stroke, or death from cardiovascular causes by 57%.

Current Intensive Insulin Replacement Regimens

The goal of physiologic insulin replacement for T1DM is accomplished with short-acting insulins that more closely mimic the sharp increase and short duration of pancreatic insulin secreted with nutrient intake. The rapid-acting insulin analog lispro has superior pharmacokinetic properties for the control of postprandial glucose. Improved postprandial glucose responses occur with twice-daily injections (conventional insulin), multiple daily insulin injections, or CSII. The use of lispro or aspart insulin reduces the frequency of between-meal hypoglycemic events, especially when it is carefully balanced with the carbohydrate content of meal.

The carbohydrate content of food does not influence glycemic control if premeal rapid-acting insulin (bolus) is adjusted to the carbohydrate content of the meal. Wide variations in carbohydrate intake do not modify long-acting (detemir or glargine) or basal insulin requirements. Insulin replacement strategies stress the importance of administering smaller doses of insulin throughout the day. This approach allows insulin doses to be changed as needed to correct hyperglycemia, supplement for additional anticipated carbohydrate intake, or subtract for exercise. Indeed, bolus-basal treatment with multiple injections is better adapted to the physiologic profiles of insulin and glucose and can therefore provide better glycemic control than the conventional 2-3 dose regimen. Age-adjusted and individualized insulin to carbohydrate ratios and insulin dosage adjustment algorithms have been developed to normalize elevated blood glucose levels and to compensate for alterations in carbohydrate intake. The use of flexible multiple daily injections and CSII in children with T1DM improves glycemic control without an increase in the incidence of severe hypoglycemia.

Hypoglycemic Reactions

Hypoglycemia is the major limitation to tight control of glucose levels. Once injected, insulin absorption and action are independent of the glucose level, thus creating a unique risk of hypoglycemia from an unbalanced insulin effect. Insulin analogs may help reduce but cannot eliminate this risk. Most children with T1DM can expect mild hypoglycemia each week, moderate hypoglycemia a few times each year, and severe hypoglycemia every few years. These episodes are usually not predictable, although exercise, delayed meals or snacks, and wide swings in glucose levels increase the risk. Infants and toddlers are at higher risk for hypoglycemia because they have more variable meals and activity levels, are unable to recognize early signs of hypoglycemia, and are limited in their ability to seek a source of oral glucose to reverse the hypoglycemia. The very young have an increased risk of permanently reduced cognitive function as a long-term sequela of severe hypoglycemia. For this reason, a more relaxed degree of glucose control is necessary until the child matures (see Table 589-9).

Hypoglycemia can occur at any time of day or night. Early symptoms and signs (mild hypoglycemia) may occur with a sudden decrease in blood glucose to levels that do not meet standard criteria for hypoglycemia in children without diabetes. The child may show pallor, sweating, apprehension or fussiness, hunger, tremor, and tachycardia, all as a result of the surge in catecholamines as the body attempts to counter the excessive insulin effect. Behavioral changes such as tearfulness, irritability, and aggression are more prevalent in children. As glucose levels decline further, cerebral glucopenia occurs with drowsiness, personality changes, mental confusion, and impaired judgment (moderate hypoglycemia), progressing to inability to seek help and seizures or coma (severe hypoglycemia). Prolonged severe hypoglycemia can result in a depressed sensorium or stroke-like focal motor deficits that persist after the hypoglycemia has resolved. Although permanent sequelae are rare, severe hypoglycemia is frightening for the child and family and can result in significant reluctance to attempt even moderate glycemic control afterward.

Important counterregulatory hormones in children include growth hormone, cortisol, epinephrine, and glucagon. The latter 2 seem more critical in the older child. Many older patients with long-standing T1DM lose their ability to secrete glucagon in response to hypoglycemia. In the young adult, epinephrine deficiency may also develop as part of a general autonomic neuropathy. This substantially increases the risk of hypoglycemia because the early warning signals of a declining glucose level are as a result of catecholamine release. Recurrent hypoglycemic episodes associated with tight metabolic control may aggravate partial counterregulatory deficiencies, producing a syndrome of hypoglycemia unawareness and reduced ability to restore euglycemia (hypoglycemia-associated autonomic failure). Avoidance of hypoglycemia allows some recovery from this unawareness syndrome.

The most important factors in the management of hypoglycemia are an understanding by the patient and family of the symptoms and signs of the reaction and an anticipation of known precipitating factors such as gym or sports activities. Tighter glucose control increases the risk. Families should be taught to look for typical hypoglycemic scenarios or patterns in the home blood glucose log, so that they may adjust the insulin dose and avert predictable episodes. A source of emergency glucose should be available at all times and places, including at school and during visits to friends. If possible, it is important to document the hypoglycemia before treating, because some symptoms may not always be from hypoglycemia. Any child suspected of having a moderate to severe hypoglycemic episode should be treated before testing. It is important not to give too much glucose; 5-10 g should be given as juice or a sugar-containing carbonated beverage or candy, and the blood glucose checked 15-20 min later. Patients, parents, and teachers should also be instructed in the administration of glucagon when the child cannot take glucose orally. An injection kit should be kept at home and school. The intramuscular dose is 0.5 mg if the child weighs less than 20 kg and 1.0 mg if more than 20 kg. This produces a brief release of glucose from the liver. Glucagon often causes emesis, which precludes giving oral supplementation if the blood glucose declines after the glucagon effects have waned. Caretakers must then be prepared to take the child to the hospital for IV glucose administration, if necessary. Minidose glucagon (10 µg/yr of age up to a maximum of 150 µg subcutaneously) is effective in treating hypoglycemia in children with blood glucose less than 60 mg/dL who fail to respond to oral glucose and remain symptomatic.

Dawn Phenomenon and Somogyi Phenomenon

There are several reasons that blood glucose levels increase in the early morning hours before breakfast. The most common is a simple decline in insulin levels. This usually results in routinely elevated morning glucose. The **dawn phenomenon** is thought to be mainly caused by overnight growth hormone secretion and increased insulin clearance. It is a normal physiologic process seen in most adolescents without diabetes, who compensate with more insulin output. A child with T1DM cannot compensate. The dawn phenomenon is usually recurrent and modestly elevates most morning glucose levels.

Rarely, high morning glucose is caused by the **Somogyi phenomenon,** a theoretical rebound from late-night or early-morning hypoglycemia, thought to be from an exaggerated counterregulatory response. It is unlikely to be a common cause, in that most children remain hypoglycemic (do not rebound) once nighttime glucose levels decline. Continuous glucose monitoring systems may help clarify ambiguously elevated morning glucose levels.

Behavioral/Psychologic Aspects and Eating Disorders

Diabetes in a child affects the lifestyle and interpersonal relationships of the entire family. Feelings of anxiety and guilt are common in parents. Similar feelings, coupled with denial and rejection, are equally common in children, particularly during the rebellious teenage years. Family conflict has been associated with poor treatment adherence and poor metabolic control among youths with T1DM. On the other hand, it has been shown that shared responsibility is consistently associated with better psychologic health, good self-care behavior, and good metabolic control, whereas responsibility assumed by either the child or parent alone does not have outcomes that are equally successful. In some cases, links of shared responsibility to health outcomes were stronger among older adolescents. However, no specific personality disorder or psychopathology is characteristic of diabetes; similar feelings are observed in families with other chronic disorders.

COGNITIVE FUNCTION

There is increasing agreement that children with T1DM are at higher risk of developing small differences in cognitive abilities compared to healthy age-matched peers. Evidence suggests that early-onset diabetes (younger than 7 yr) is associated with cognitive difficulties compared to late-onset diabetes and healthy controls. The cognitive difficulties observed were primarily learning and memory skills (both verbal and visual) and attention/executive function skills. It is likely that the impact of diabetes on pediatric cognition appears shortly after diagnosis. Indeed, it has been observed that early-onset diabetes and longer duration of diabetes in children with diabetes adversely affect their school performance and educational achievements.

COPING STYLES

Children and adolescents with T1DM are faced with a complex set of developmental changes as well as shifting burdens of the disease. Adjustment problems might affect psychologic well-being and the course of the disease by impacting self-management and leading to poor metabolic control. Coping styles refer to typical habitual preferences for ways of approaching problems and might be regarded as strategies that people generally use to cope across a wide range of stressors. Problem-focused coping refers to efforts directed toward rational management of a problem, and it is aimed at changing the situation causing distress. On the other hand, emotion-focused coping implies efforts to reduce emotional distress caused by the stressful event and to manage or regulate emotions that might accompany or result from the stressor. In adolescents with diabetes, avoidance coping and venting emotions have been found to predict poor illness-specific self-care behavior and poor metabolic control. Patients who use more mature defenses and exhibit greater adaptive capacity are more likely to adhere to their regimen. Coping strategies seem to be age dependent, with adolescents using more avoidance coping than younger children with diabetes.

NONADHERENCE

Family conflict, denial, and feelings of anxiety or loss of control find expression in nonadherence to instructions regarding nutritional and insulin therapy and in noncompliance with self-monitoring. When adolescents perceive their parents' involvement as criticism, or when they externalize behavior problems, such behaviors interfere with adherence and may result in deterioration of glycemic control. Such behaviors are very common, whereas episodes of deliberate overdosage with insulin resulting in hypoglycemia, or omission of insulin resulting in ketoacidosis, are far less prevalent. They may, however, be pleas for psychologic help or be manipulative attempts to escape an environment perceived as undesirable or intolerable; occasionally, they may be manifestations of suicidal intent. Frequent admissions to the hospital for ketoacidosis or hypoglycemia should arouse suspicion of an underlying emotional conflict. Overprotection on the part of parents is common and often is not in the best interest of the adolescent patient. Feelings of being different or of being alone, or both, are common and must be acknowledged, but may be addressed by tailoring the insulin administration and timing of meals and blood sugar testings in order to allow for a more individualized lifestyle. Families and patients worry about the risk of complications from diabetes, aggregating what they know about type 1 and type II diabetes, and worry about the decreased life span. Unfortunately, misinformation abounds about the risks of the development of diabetes in siblings or offspring and of pregnancy in young diabetic women. Even appropriate information may cause further anxiety.

All of these issues must be spoken about at the outset, and many of these problems can be averted through continued empathic counseling based on correct information, focusing on normality and on planning to be a productive member of society. Recognizing the potential impact of these problems, peer discussion groups have been organized in many locales; feelings of isolation and frustration tend to be lessened by the sharing of common problems. Summer camps for diabetic children afford an excellent opportunity for learning and sharing under expert supervision. Education about the pathophysiology of diabetes, insulin dose, technique of administration, nutrition, exercise, and hypoglycemic reactions can be reinforced by medical and paramedical personnel. The presence of numerous peers with similar problems offers new insights to the diabetic child. Residential treatment for children and adolescents with difficult to manage T1DM is an option available only in some centers.

ANXIETY AND DEPRESSION

It has been shown that there are significant correlations between poor metabolic control and depressive symptoms, a high level of anxiety, or a previous psychiatric diagnosis. In a similar way, poor metabolic control is related to higher levels of personal, social, school maladjustment, or family environment dissatisfaction. It is estimated that 20-26% of adolescent patients may develop major depressive disorder. The prevalence of depression is 2-fold greater than controls in children with diabetes and 3-fold greater in adolescents. The course characteristics of depression in young diabetic subjects and psychiatric control subjects appear to be similar; however, eventual propensity of diabetic youths for more protracted depressions is greater and there is a higher risk of recurrence among young diabetic females. On balance, anxiety and depression play an important and complex role in T1DM; their relationship to metabolic control does not yet appear clear. Therefore, the healthcare providers managing a child or adolescent with diabetes should be aware of their pivotal role as counselor and advisor and should closely monitor the mental health of patients with diabetes.

FEAR OF SELF-INJECTING AND SELF-TESTING

Extreme fear of self-injecting insulin (injection phobia) is likely to compromise glycemic control as well as emotional well-being. Likewise, fear of finger pricks can be a source of distress and may seriously hamper self-management. Children and adolescents may either omit insulin dosing or refuse to rotate their injection sites because repeated injection in the same site is associated with less pain sensation. Failure to rotate injection sites results in subcutaneous scar formation (lipohypertrophy). Insulin injection into the lipohypertrophic skin is usually associated with poor insulin absorption and/or insulin leakage with resultant suboptimal glycemic control. Children and adolescents with injection phobia and fear of self-testing can be counseled by a trained behavioral therapist and benefit from such techniques as desensitization and biofeedback to attenuate pain sensation and psychologic distress associated with these procedures. Another possibility is to consider using an indwelling subcutaneous soft cannula to minimize the discomfort of repeated injections.

EATING DISORDERS

Treatment of T1DM involves constant monitoring of food intake. In addition, improved glycemic control is sometimes associated with increased weight gain. In adolescent females, these 2 factors, along with individual, familial, and socioeconomic factors, can lead to an increased incidence of both nonspecific and specific eating disorders, which can disrupt glycemic control and increase the risk of long-term complications. Eating disorders and subthreshold eating disorders are almost

twice as common in adolescent females with T1DM as in their nondiabetic peers. The reports of the frequencies of specific (anorexia or bulimia nervosa) eating disorders vary from 1.0-6.9% among female patients with T1DM. The prevalence of nonspecific and subthreshold eating disorders is 9% and 14%, respectively. Approximately 11% of T1DM adolescent females take less insulin than prescribed in order to lose weight. Among adolescent females with an eating disorder, approximately 42% of patients misuse insulin, whereas the estimates of insulin misuse prevalence in subthreshold and nondisordered eating groups are 18% and 6%, respectively. Although there is little information regarding the prevalence of eating disorders among male adolescents with T1DM, available data suggest normal eating attitudes in most. Among healthy adolescent males who participate in wrestling, however, the drive to lose weight has led to the seasonal, transient development of abnormal eating attitudes and behaviors, which may lead to insulin dose omission in order to lose weight.

When behavioral/psychologic problems and/or eating disorders are assumed to be responsible for poor adherence with the medical regimen, referral for psychologic evaluation and management is indicated. Behavioral therapists and psychologists usually form part of the pediatric diabetes team in most centers and can help assess and manage emotional and behavioral disorders in diabetic children. Evaluation of nurse-delivered motivational enhancement with and without cognitive behavior therapy in adults revealed the combined therapy resulted in modest improvement in glycemic control. However, motivational enhancement therapy alone did not improve glycemic control. While in some studies the effect of therapist-delivered motivational enhancement therapy on glycemic control in adolescents with T1DM lasted as long as intensive individualized counseling continued, in other studies, motivational interviewing was shown to be an effective method of facilitating changes in a teenager's behavior with T1DM with corresponding improvement in glycemic control.

Management During Infections

Although infections are no more common in diabetic children than in nondiabetic ones, they can often disrupt glucose control and may precipitate DKA. In addition, the diabetic child is at increased risk of dehydration if hyperglycemia causes an osmotic diuresis or if ketosis causes emesis. Counterregulatory hormones associated with stress blunt insulin action and elevate glucose levels. If anorexia occurs from ketosis, lack of caloric intake increases the risk of hypoglycemia. Although children younger than 3 yr of age tend to become hypoglycemic and older children tend toward hyperglycemia, the overall effect is unpredictable. Therefore, frequent blood glucose monitoring and adjustment of insulin doses are essential elements of sick day guidelines (Table 589-10).

The overall goals are to maintain hydration, control glucose levels, and avoid ketoacidosis. This can usually be done at home if proper sick day guidelines are followed and with telephone contact with healthcare providers. The family should seek advice if home treatment does not control ketonuria, hyperglycemia, or hypoglycemia, or if the child shows signs of dehydration. A child with large ketonuria and emesis should be seen in the emergency department for a general examination, to evaluate hydration, and to determine whether ketoacidosis is present by checking serum electrolytes, glucose, pH, and total CO_2. A child whose blood glucose declines to less than 50-60 mg/dL (2.8-3.3 mmol/L) and who cannot maintain oral intake may need IV glucose, especially if further insulin is needed to control ketonemia.

Management During Surgery

Surgery can disrupt glucose control in the same way as can intercurrent infections. Stress hormones associated with the underlying condition as well as with surgery itself cause insulin resistance. This increases glucose levels, exacerbates fluid losses, and may initiate DKA. On the other hand, caloric intake is usually restricted, which decreases glucose levels. The net effect is as difficult to predict as during an infection. Vigilant monitoring and frequent insulin adjustments are required to maintain euglycemia and avoid ketosis.

Maintaining glucose control and avoiding DKA are best accomplished with IV insulin and fluids. A simple insulin adjustment scale based on the patient's weight and blood glucose level can be used in most situations (Table 589-11). The IV insulin is continued after surgery as the child begins to take oral fluids; the IV fluids can be steadily decreased as oral intake increases. When full oral intake is achieved, the IV may be capped and subcutaneous insulin begun. When surgery is elective, it is best performed early in the day, allowing the patient maximal recovery time to restart oral intake and subcutaneous insulin therapy. When elective surgery is brief (less than 1 hr) and full oral intake is expected shortly afterward, one may simply monitor the blood glucose hourly and give a dose of insulin analog according to the child's home glucose correction scale. If glargine or detemir is used as the basal insulin, a full dose is given the evening before planned surgery. If NPH or Lente is used, one half of the morning dose is given before surgery. The child should not be discharged until blood glucose levels are stable and oral intake is tolerated.

Table 589-11 Guidelines for Intravenous Insulin Coverage During Surgery

BLOOD GLUCOSE LEVEL (mg/dL)	INSULIN INFUSION (units/kg/hr)	BLOOD GLUCOSE MONITORING
<120	0.00	1 hr
121-200	0.03	2 hr
200-300	0.06	2 hr
300-400	0.08	1 hr*
400	0.10	1 hr*

An infusion of 5% glucose and 0.45% saline solution with 20 mEq/L of potassium acetate is given at 1.5 times maintenance rate.
*Check urine ketones.

Table 589-10 Guidelines for Sick Day Management

URINE KETONE STATUS	GLUCOSE TESTING AND EXTRA RAPID-ACTING INSULIN: Insulin	GLUCOSE TESTING AND EXTRA RAPID-ACTING INSULIN: Correction Doses*	COMMENT
Negative or small†	q2hr	q2hr for glucose >250 mg/dL	Check ketones every other void
Moderate to large‡	q1hr	q1hr for glucose >250 mg/dL	Check ketones each void; go to hospital if emesis occurs

Basal insulin: glargine or detemir basal insulin should be given at the usual dose and time. NPH and Lente should be reduced by half if blood glucose <150 mg/dL and the oral intake is limited.
Oral fluids: sugar-free if blood glucose >250 mg/dL (14 mmol/L); sugar-containing if blood glucose <250 mg/dL.
Call physician or nurse if blood glucose remains elevated after 3 extra doses; if blood glucose remains less than 70 mg/dL and child cannot take oral supplement; if dehydration occurs.
*Give insulin based on individualized dosing schedule. Also give usual dose for carbohydrate intake if glucose >150 mg/dL.
†For home serum ketones <1.5 mmol/L per commercial kit.
‡For home serum ketones >1.5 mmol/L.

LONG-TERM COMPLICATIONS: RELATION TO GLYCEMIC CONTROL

Complications of DM can be divided into 3 major categories: (1) microvascular complications, specifically, retinopathy and nephropathy; (2) macrovascular complications, particularly accelerated coronary artery disease, cerebrovascular disease, and peripheral vascular disease; and (3) neuropathies, both peripheral and autonomic, affecting a variety of organs and systems (Table 589-12). In addition, cataracts may occur more frequently.

Diabetic retinopathy is the leading cause of blindness in the United States in adults age 20-65 yr. The risk of diabetic retinopathy after 15 yr duration of diabetes is 98% for individuals with T1DM and 78% for those with T2DM. Rates for diabetic retinopathy range from close to 15% to up to 30%. Lens opacities (caused by glycation of tissue proteins and activation of the polyol pathway) are present in at least 5% of those younger than age 19 yr. The metabolic control has an impact on the development of this complication, as prevalence rates are substantially higher with increased duration of diabetes, and higher HbA_{1c}, blood pressure, and cholesterol. Independent of duration, the prevalence of diabetic retinopathy is higher in T1DM. However, genetic factors also have a role, because only 50% of patients develop proliferative retinopathy. The earliest clinically apparent manifestations of diabetic retinopathy are classified as nonproliferative or background diabetic retinopathy—microaneurysms, dot and blot hemorrhages, hard and soft exudates, venous dilation and beading, and intraretinal microvascular abnormalities. These changes do not impair vision. The more severe form is proliferative diabetic retinopathy, which manifests by neovascularization, fibrous proliferation, and preretinal and vitreous hemorrhages. Proliferative retinopathy, if not treated, is relentlessly progressive and impairs vision, leading to blindness. The mainstay of treatment is panretinal laser photocoagulation. In advanced diabetic eye disease—manifested by severe vitreous hemorrhage or fibrosis, often with retinal detachment—vitrectomy is an important therapeutic modality. Eventually, the eye disease becomes quiescent, a stage termed involutional retinopathy. A separate subtype of retinopathy is diabetic maculopathy, which is manifested by severe macular edema impairing central vision, for which focal laser photocoagulation may be effective.

Guidelines suggest that diabetic patients have an initial dilated and comprehensive examination by an ophthalmologist shortly after the diagnosis of diabetes is made in patients with T2DM, and within 3-5 yr after the onset of T1DM (but not before age 10 yr). Any patients with visual symptoms or abnormalities should be referred for ophthalmologic evaluation. Subsequent evaluations for both T1DM and T2DM patients should be repeated annually by an ophthalmologist who is experienced in diagnosing the presence of diabetic retinopathy and is knowledgeable about its management (see Table 589-12).

Diabetic nephropathy is the leading known cause of end-stage renal disease (ESRD) in the United States. Most ESRD from diabetic nephropathy is preventable. Diabetic nephropathy affects 20-30% of patients with T1DM and 15-20% of T2DM patients 20 yr after onset. The mean 5 yr life expectancy for patients with diabetes-related ESRD is less than 20%. The increased mortality risk in long-term T1DM may be due to nephropathy, which may account for approximately 50% of deaths. The risk of nephropathy increases with duration of diabetes (up until 25-30 yr duration, after which this complication rarely begins), degree of metabolic control, and genetic predisposition to essential hypertension. Only 30-40% of patients affected by T1DM eventually experience ESRD. The glycation of tissue proteins results in glomerular basement membrane thickening. The course of diabetic nephropathy is slow. An increased urinary albumin excretion rate of 30-300 mg/24 hr (20-200 µg/min)—*microalbuminuria*—can be detected and constitutes an early stage of nephropathy from intermittent to persistent (incipient), which is commonly associated with glomerular hyperfiltration and blood pressure elevation. As nephropathy evolves to early overt stage with proteinuria (albumin excretion rate >300 mg/24 hr, or >200 µg/min), it is accompanied by hypertension. Advanced-stage nephropathy is defined by a progressive decline in renal function (declining glomerular filtration rate and elevation of serum blood urea and creatinine), progressive proteinuria, and

Table 589-12 Screening Guidelines

	WHEN TO COMMENCE SCREENING	FREQUENCY	PREFERRED METHOD OF SCREENING	OTHER SCREENING METHODS	POTENTIAL INTERVENTION
Retinopathy	After 5 yr duration in prepubertal children, after 2 yr in pubertal children	1-2 yearly	Fundal photography	Fluorescein angiography, mydriatic ophthalmoscopy	Improved glycemic control, laser therapy
Nephropathy	After 5 yr duration in prepubertal children, after 2 yr in pubertal children	Annually	Spot urine sample for albumin : creatinine ratio	24 hr excretion of albumin, urinary albumin : creatinine ratio	Improved glycemic control, blood pressure control, ACE inhibitors
Neuropathy	Unclear in children; adults at diagnosis in T2DM and 5 yr after diagnosis in T1DM	Unclear	Physical examination	Nerve conduction, thermal and vibration threshold, pupillometry, cardiovascular reflexes	Improved glycemic control
Macrovascular disease	After age 2 yr	Every 5 yr	Lipids	Blood pressure	Statins for hyperlipidemia Blood pressure control
Thyroid disease	At diagnosis	Every 2-3 yr or more frequently based on symptoms or the presence of antithyroid antibodies	TSH	Thyroid peroxidase, thyroglobulin antibodies	Thyroxine
Celiac disease	At diagnosis	Every 2-3 yr	Tissue transglutaminase, endomysial antibody	Transglutaminase antibodies	Gluten-free diet

ACE, angiotensin-converting enzyme; T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus; TSH, thyroid-stimulating hormone.

From Glastras SJ, Mohsin F, Donaghue KC: Complications of diabetes mellitus in childhood, Pediatr Clin North Am *52:1735–1753, 2005.*

hypertension. Progression to ESRD is recognized by the appearance of uremia, the nephritic syndrome, and the need for renal replacement (transplantation or dialysis).

Screening for diabetic nephropathy is a routine aspect of diabetes care (see Table 589-12). The American Diabetes Association recommends yearly screening for individuals with T2DM and yearly screening for those with T1DM after 5 yr duration of disease (but not before puberty). A random spot urine sample for albumin to creatinine ratio is obtained. Abnormal results should be confirmed by 2 additional specimens on separate days because of the high variability of albumin excretion in patients with diabetes. Short-term hyperglycemia, strenuous exercise, urinary tract infections, marked hypertension, heart failure, and acute febrile illness can cause transient elevation urinary albumin excretion. There is marked day-to-day variability in albumin excretion, so at least 2 of 3 collections done in a 3-6 mo period should show elevated levels before microalbuminuria is diagnosed and treatment is started. Once albuminuria is diagnosed, a number of factors attenuate the effect of hyperfiltration on kidneys: (1) meticulous control of hyperglycemia, (2) aggressive control of systemic blood pressure, (3) selective control of arteriolar dilation by use of angiotensin-converting enzyme inhibitors (thus decreasing transglomerular capillary pressure), and (4) dietary protein restriction (because high protein intake increases the renal perfusion rate). Tight glycemic control will delay the progression of microalbuminuria and slow the progression of diabetic nephropathy. Previous extensive therapy of diabetes has a persistent benefit for 7-8 yr and may delay or prevent the development of diabetic nephropathy.

DIABETIC NEUROPATHY

Both the peripheral and autonomic nervous systems can be involved, and adolescents with diabetes can show early evidence of neuropathy. This complication can be traced to the metabolic effects of hyperglycemia and/or other effects of insulin deficiency on the various constituents of the peripheral nerve. The polyol pathway, nonenzymatic glycation, and/or disturbances of myoinositol metabolism affecting 1 or more cell types in the multicellular constituents of the peripheral nerve appear likely to have an inciting role. The role of other factors, such as possible direct neurotrophic effects of insulin, insulin-related growth factors, nitric oxide, and stress proteins, seems to be relevant. Peripheral neuropathy may first present in some adolescents with a long-standing history of diabetes. Using quantitative sensory testing, abnormal cutaneous thermal perception is a common finding in both upper and lower limbs in neurologically asymptomatic young diabetic patients. Heat-induced pain threshold in the hand is correlated with the duration of the diabetes. There is no correlation between quantitative sensory testing scores and metabolic control. Subclinical motor nerve impairment as manifested by reduced sensory nerve conduction velocity and sensory nerve action potential amplitude can be detected during late puberty and after puberty in approximately 10% of adolescents. Poor metabolic control during puberty appears to induce deteriorating peripheral neural function in young patients. An early sign of autonomic neuropathy such as decreased heart rate variability may present in adolescents with a history of long-standing disease and poor metabolic control. A number of therapeutic strategies have been attempted with variable results. These treatment modalities include (1) improvement in metabolic control, (2) use of aldose reductase inhibitors to reduce by-products of the polyol pathway, (3) use of α-lipoic acid (an antioxidant) that enhances tissue nitric oxide and its metabolites, (4) use of anticonvulsants (e.g., lorazepam, valproate, gabapentin, carbamazepine, pregabalin, phenytoin, tiagabine, and topiramate) for treatment of neuropathic pain, and (5) antidepressants (amitriptyline, imipramine, and selective serotonin reuptake inhibitors). Additional medications include antiarrhythmics such as lidocaine, topical analgesics, and nonsteroidal antiinflammatory drugs.

Other quite rarely noted complications in diabetic children include dwarfism associated with a glycogen-laden enlarged liver **(Mauriac syndrome),** osteopenia, and a syndrome of limited joint mobility associated with tight, waxy skin; growth impairment; and maturational delay. The Mauriac syndrome is related to chronic underinsulinization; it is much less common since longer-acting insulins have become available. Clinical features of Mauriac syndrome include moon face, protuberant abdomen, proximal muscle wasting, and enlarged liver from fat and glycogen infiltration. The syndrome of limited joint mobility is frequently associated with the early development of diabetic microvascular complications, such as retinopathy and nephropathy, which may appear before 18 yr of age. In the past decade or two, the prevalence of limited joint mobility has significantly decreased, which is attributed to the improved overall metabolic control of children and adolescents with T1DM.

PROGNOSIS

T1DM is a serious, chronic disease. It has been estimated that the average life span of individuals with diabetes is approximately 10 yr shorter than that of the nondiabetic population. Although diabetic children eventually attain a height within the normal adult range, puberty may be delayed, and the final height may be less than the genetic potential. From studies in identical twins, it is apparent that despite seemingly satisfactory control, the diabetic twin manifests delayed puberty and a substantial reduction in height when onset of disease occurs before puberty. These observations indicate that, in the past, conventional criteria for judging control were inadequate and that adequate control of T1DM was almost never achieved by routine means.

The introduction of portable devices (insulin pumps) that can be programmed to provide CSII with meal-related boluses is 1 approach to the resolution of these long-term problems. In selected individuals, nearly normal patterns of blood glucose and other indices of metabolic control, including HbA_{1c}, have been maintained for several years. This approach, however, should be reserved for highly motivated persons committed to rigorous self-monitoring of blood glucose who are alert to the potential complications, such as mechanical failure of the infusion device causing hyperglycemia or hypoglycemia and to infection at the site of catheter insertion.

The changing pattern of metabolic control is having a profound influence on reducing the incidence and the severity of certain complications. For example, after 20 yr of diabetes, there is a decline in the incidence of nephropathy in T1DM in Sweden among children whose disease was diagnosed in 1971-1975 compared with in the preceding decade. In addition, in most patients with microalbuminuria in whom it was possible to obtain good glycemic control, microalbuminuria disappeared. This improved prognosis is directly related to metabolic control.

PANCREAS AND ISLET TRANSPLANTATION AND REGENERATION

In an attempt to cure T1DM, transplantation of a segment of the pancreas or of isolated islets has been performed in adults. These procedures are both technically demanding and associated with the risks of disease recurrence and complications of rejection or its treatment by immunosuppression. Long-term complications of immunosuppression include the development of malignancy. Some antirejection drugs, notably cyclosporine and tacrolimus, are toxic to the islets of Langerhans, impairing insulin secretion and even causing diabetes. Hence, segmental pancreas transplantation is generally only performed in association with transplantation of a kidney for a patient with ESRD due to diabetic nephropathy in which the immunosuppressive regimen is indicated for the renal transplantation. Several thousand such transplants have been performed in adults. With experience and newer immunosuppressive agents, functional survival of the pancreatic graft may be achieved for up to several years, during which time patients may be in metabolic control with no or minimal exogenous insulin and reversal of some of the microvascular complications. However, because children and adolescents with DM are not likely to have ESRD from their diabetes, pancreas transplantation as a primary treatment in children cannot be recommended.

Islet cell transplantation is challenging because of limited survival of the transplanted cells and because of rejection. Research continues to improve techniques for the yield, viability, and reduction of

immunogenicity of the islets of Langerhans for transplantation. An islet transplantation strategy **(Edmonton protocol)** infused isolated pancreatic islets into the portal vein of a group of adults with T1DM, along with immunosuppressive medications that had lower side-effect profiles than other drugs. While lasting insulin independence was initially low, engraftment and insulin independence have improved over the last decade, and over a thousand patients having undergone the procedure. There has been improved islet engraftment by the use of improved induction and maintenance immunosuppression. Still, in 5-yr follow-up studies, only 1 in 10 maintain insulin independence, with an average duration of insulin independence in all of only about 15 mo. Long-term challenges remain the toxicity of immunosuppression, the limited procurement of viable tissue, and funding and limitations of engraftment itself.

Alternative means of generating β cells are being sought from islet expansion, encapsulated islet xenografts, human islet cell-lines, and stem cells. Regeneration of islets is an approach that could potentially cure T1DM because β-cell mass is actually dynamically regulated.

589.3 Type 2 Diabetes Mellitus

Britta M. Svoren and Nicholas Jospe

Formerly known as non–insulin dependent diabetes or adult-onset diabetes, T2DM is a heterogeneous disorder, characterized by peripheral insulin resistance and failure of the β cell to keep up with increasing insulin demand. Patients with T2DM have relative rather than absolute insulin deficiency. Generally, they are not ketosis prone, but ketoacidosis may develop in some circumstances. The specific etiology is not known, but these patients do not have autoimmune destruction of β cells, nor do they have any of the known causes of secondary diabetes.

NATURAL HISTORY

T2DM is considered a polygenic disease aggravated by environmental factors, such as low physical activity and excessive caloric intake. Most patients are obese, although the disease can occasionally be seen in normal weight individuals. Asians in particular appear to be at risk for T2DM at lower degrees of total adiposity. Some patients may not necessarily meet overweight or obese criteria for age and gender despite abnormally high percentage of body fat in the abdominal region. Obesity, in particular, central obesity, is associated with the development of insulin resistance. In addition, patients who are at risk for developing T2DM exhibit decreased glucose-induced insulin secretion. Obesity does not lead to the same degree of insulin resistance in all individuals and even those who develop insulin resistance do not necessarily exhibit impaired β-cell function. Thus, many obese individuals have some degree of insulin resistance but compensate for it by increasing insulin secretion. Those individuals who are unable to adequately compensate for insulin resistance by increasing insulin secretion, develop IGT and impaired fasting glucose (usually, although not always, in that order). Hepatic insulin resistance leads to excessive hepatic glucose output (failure of insulin to suppress hepatic glucose output), while skeletal muscle insulin resistance leads to decreased glucose uptake in a major site of glucose disposal. Over time hyperglycemia worsens, a phenomenon that has been attributed to the deleterious effect of chronic hyperglycemia (glucotoxicity) or chronic hyperlipidemia (lipotoxicity) on β-cell function and is often accompanied by increased triglyceride content and decreased insulin gene expression. At some point, blood glucose elevation meets the criteria for diagnosis of T2DM (see Table 589-2), but most patients with T2DM remain asymptomatic for months to years after this point because hyperglycemia is moderate and symptoms are not as dramatic as the polyuria and weight loss accompanying T1DM. Weight gain may even continue. The prolonged hyperglycemia may be accompanied by the development of microvascular and macrovascular complications. In time, β-cell function can decrease to the point that the patient has absolute insulin deficiency and becomes dependent on exogenous insulin. In T2DM, insulin deficiency is rarely absolute, so patients usually do not need insulin to survive. Nevertheless, glycemic control can be improved by exogenous insulin. Although DKA is uncommon in patients with T2DM, it can occur and is usually associated with the stress of another illness such as severe infection. DKA tends to be more common in African-American patients than in other ethnic groups. Although it is generally believed that autoimmune destruction of pancreatic β cells does not occur in T2DM, autoimmune markers of T1DM—namely, glutamic acid decarboxylase antibody, ICA512, and insulin-associated autoantibody—may be positive in up to one third of the cases of adolescent T2DM. The presence of these autoimmune markers does not rule out T2DM in children and adolescents. At the same time, because of the general increase in obesity, the presence of obesity does not preclude the diagnosis of T1DM. Although the majority of newly diagnosed children and adolescents can be confidently assigned a diagnosis of T1DM or T2DM, a few exhibit features of both types and are difficult to classify.

EPIDEMIOLOGY

National Health and Nutritional Examination Surveys data (from 1999-2002) show that the prevalence of T2DM in 12-19 yr olds in the United States is 1.46 in 1,000. The Southeastern Aerosol Research and Characterization (SEARCH) study found that the prevalence of type 2 diabetes in the 10-19 yr old age group in the United States was 15% in 2001 and it is likely that this proportion has increased over time. Certain ethnic groups appear to be at higher risk; for example, Native Americans, Hispanic Americans, and African-Americans (in that order) have higher incidence rates than white Americans. Although a majority of children presenting with diabetes still have T1DM, the percentage of children presenting with T2DM is increasing and represents up to 50% of the newly diagnosed children in some centers.

Prevalence in the rest of the world varies widely and accurate data are not available for many countries, but it is clear that the prevalence is increasing in every part of the world. Asians in general seem to develop T2DM at lower body mass index levels than Europeans. In conjunction with their low incidence of type 1 diabetes, this means that T2DM accounts for a higher proportion of childhood diabetes in many Asian countries.

The epidemic of T2DM in children and adolescents parallels the emergence of the obesity epidemic. Although obesity itself is associated with insulin resistance, diabetes does not develop until there is some degree of failure of insulin secretion. Thus, when measured, insulin secretion in response to glucose or other stimuli is always lower in persons with T2DM than in control subjects matched for age, sex, weight, and equivalent glucose concentration.

GENETICS

T2DM has a strong genetic component; concordance rates among identical twins are in the 60-90% range. It should be kept in mind, however, that twinning itself increases the risk of T2DM (because of intrauterine growth restriction) and this may distort estimates of genetic risk. In at least 1 study from Denmark, both monozygotic and dizygotic twins have a lifetime concordance of T2DM of around 70%, indicating that shared environmental factors (including the prenatal environment) may play a large role in the development of T2DM. The genetic basis for T2DM is complex and incompletely defined; no single identified defect predominates as does the HLA association with T1DM. Genomewide association studies have now identified certain genetic polymorphisms that are associated with increased T2DM risk in most populations studied; the most consistently identified are variants of the TCF7L2 (transcription factor 7–like 2) gene, which may have a role in β-cell function. Other identified risk alleles include variants in *PPARG* and *KCNJ11* as well as many others. But to date, all these identified variants explain only a small portion (probably less than 20%) of the population risk of diabetes and in many cases the mechanism by which these polymorphisms confer risk of T2DM is not clear.

EPIGENETICS AND FETAL PROGRAMMING

Low birthweight and intrauterine growth restriction are associated with increased risk of T2DM. This risk appears to be higher in

low-birthweight infants who gain weight more rapidly in the 1st few years of life. These findings have led to the formulation of the "thrifty phenotype" hypothesis, which postulates that poor fetal nutrition somehow programs these children to maximize storage of nutrients and makes them more prone to future weight gain and development of diabetes. Epigenetic modifications may play a role in this phenomenon, but the detailed molecular mechanisms involved have yet to be determined. Whatever the exact mechanism, prenatal and early childhood environments play an important role in the pathogenesis of T2DM and may do so by epigenetic modification of the DNA (in addition to other factors).

ENVIRONMENTAL AND LIFESTYLE-RELATED RISK FACTORS

Obesity is the most important lifestyle factor associated with development of T2DM. This, in turn, is associated with the intake of high-energy foods, physical inactivity, TV viewing ("screen time"), and low socioeconomic status (in developed countries). Maternal smoking also increases the risk of diabetes and obesity in the offspring. Interestingly, smoking by young adults also increases their own risk of diabetes by as yet unknown mechanisms. In addition, sleep deprivation and psychosocial stress are associated with increased risk of obesity in childhood and with IGT in adults, possibly via overactivation of the hypothalamic-pituitary-adrenal axis. Many antipsychotics (especially the atypical antipsychotics like olanzapine and quetiapine) and antidepressants (both tricyclic antidepressants and newer antidepressants like fluoxetine and paroxetine) induce weight gain. In addition to the risk conferred by increased obesity, some of these medications may also have a direct role in causing insulin resistance, β-cell dysfunction, leptin resistance, and activation of inflammatory pathways. To complicate matters further, there is evidence that schizophrenia and depression themselves increase the risk of T2DM and the metabolic syndrome, independent of the risk conferred by drug treatment. As a result, both obesity and T2DM are more prevalent in this population, and with increasing use of antipsychotics and antidepressants in the pediatric population, this association is likely to become stronger.

CLINICAL FEATURES

In the United States, T2DM in children is more likely to be diagnosed in Native American, Hispanic American, and African-American youth, with the highest incidence being reported in Pima Indian youth. While cases may be seen as young as 6 yr of age, most are diagnosed in adolescence and incidence increases with increasing age. Family history of T2DM is present in practically all cases. Typically, patients are obese and present with mild symptoms of polyuria and polydipsia, or are asymptomatic and detected on screening tests. Presentation with DKA occurs in up to 10% of cases. Physical examination frequently reveals the presence of acanthosis nigricans, most commonly on the neck and in other flexural areas. Other findings may include striae and an increased waist : hip ratio. Laboratory testing reveals elevated HbA_{1c} levels. Hyperlipidemia characterized by elevated triglycerides and low-density lipoprotein cholesterol levels is commonly seen in patients with T2DM at diagnosis. Consequently, lipid screening is indicated in all new cases of T2DM. Because hyperglycemia develops slowly and patients may be asymptomatic for months or years after they develop T2DM, screening for T2DM is recommended in high-risk children (Table 589-13). The American Diabetes Association recommends that all youth who are overweight and have at least 2 other risk factors be tested for T2DM beginning at age 10 yr or at the onset of puberty and every 2 yr after that. Risk factors include family history of T2DM in 1st- or 2nd-degree relatives, history of gestational diabetes in the mother, belonging to certain ethnic groups (i.e., Native American, African-American, Hispanic, or Asian/Pacific Islander groups) and having signs of insulin resistance (e.g., acanthosis nigricans, hypertension, dyslipidemia, or polycystic ovary syndrome). The current recommendation is to use fasting blood glucose as a screening test, but some authorities now recommend that HbA_{1c} be used as a screening tool. In borderline or asymptomatic cases, the diagnosis may be confirmed using a standard oral glucose tolerance test, but this test is not required

Table 589-13 Testing for Type 2 Diabetes in Children

- Criteria*
  - Overweight (body mass index >85th percentile for age and sex, weight for height >85th percentile, or weight >120% of ideal for height)
  - *Plus*
  - Any 2 of the following risk factors:
    - Family history of type 2 diabetes in 1st- or 2nd-degree relative
    - Race/ethnicity (Native American, African-American, Hispanic, Asian/Pacific Islander)
    - Signs of insulin resistance or conditions associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, polycystic ovary syndrome)
- Age of initiation: age 10 yr or at onset of puberty if puberty occurs at a younger age
- Frequency: every 2 yr
- Test: fasting plasma glucose preferred

*Clinical judgment should be used to test for diabetes in high-risk patients who do not meet these criteria.

From Type 2 diabetes in children and adolescents. American Diabetes Association, Diabetes Care *23:386, 2000. Reproduced by permission.*

if typical symptoms are present or fasting plasma glucose or HbA_{1c} is clearly elevated on 2 separate occasions.

TREATMENT

Type 2 diabetes is a progressive syndrome that gradually leads to complete insulin deficiency during the patient's life. A systematic approach for treatment of T2DM should be implemented according to the natural course of the disease, including adding insulin when hypoglycemic oral agent failure occurs. Nevertheless, lifestyle modification (diet and exercise) is an essential part of the treatment regimen, and consultation with a dietitian is usually necessary.

There is no particular dietary or exercise regimen that has been conclusively shown to be superior but most centers recommend a low-calorie, low-fat diet and 30-60 min of physical activity at least 5 times/wk. Screen time should be limited to 1-2 hr/day. Children with T2DM often come from household environments with a poor understanding of healthy eating habits. Commonly observed behaviors include skipping meals, heavy snacking, and excessive daily television viewing, video game playing, and computer use. Adolescents engage in non–appetite-based eating (i.e., emotional eating, television-cued eating, boredom) and cyclic dieting ("yo-yo" dieting). Treatment in these cases is frequently challenging and may not be successful unless the entire family buys into the need to change their unhealthy lifestyle.

It is recommended that oral hypoglycemic agents be introduced at the time of diagnosis (Table 589-14). Patients who present with DKA or with markedly elevated HbA_{1c} (>9.0%) will require treatment with insulin using protocols similar to those used for treating T1DM. Once blood glucose levels are under control, most cases can be managed with oral hypoglycemic agents and lifestyle interventions, but some patients will continue to require insulin therapy.

The most commonly used and the only FDA-approved oral agent for the treatment of T2DM in children and adolescents is metformin. Renal function must be assessed before starting metformin as impaired renal function has been associated with potentially fatal lactic acidosis. Significant hepatic dysfunction is also a contraindication to metformin use, although mild elevations in liver enzymes may not be an absolute contraindication. The usual starting dose is 500 mg once daily. This may be increased to a maximum dose of 2,000 mg/day. Abdominal symptoms are common early in the course of treatment, but in most cases they will resolve with time.

Other agents such as thiazolidinediones, sulfonylureas, acarbose, pramlintide, and incretin mimetics are being used routinely in adults but are not used as commonly in pediatrics. Sulfonylureas are widely used in adults, but experience in pediatrics is limited. Sulfonylureas cause insulin release by closing the potassium channel (K_{ATP}) on β

Table 589-14 Oral Hypoglycemic Agents

DRUG	MECHANISM OF ACTION	DURATION OF BIOLOGIC EFFECT (hr)	USUAL DAILY DOSE (mg)	DOSES/DAY	SIDE EFFECTS	CAUTION
Biguanide	Insulin sensitizer				Gastrointestinal disturbance, lactic acidosis	Avoid in hepatic or renal impairment
Metformin			1500-2500	2-3		
Sulfonylureas						
1st generation						
Acetohexamide		12-18	500-750	1 or divided		
Chlorpropamide		27-72	250-500	1		
Tolbutamide		14-16	1000-2000	1 or divided		
2nd generation						
Glipizide		14-16	2.5-10 XL: 5-10	1 or divided 1		
Glyburide		20-24+	2.5-10	1 or divided		
Glimepiride		24+	2-4	1		
Glitinides	Promote insulin secretion					Titrate carefully in renal or hepatic dysfunction
Repaglinide		≤24	2-16	3		
Nateglinide		4	360	3		
α-Glucosidase inhibitors	Slow hydrolysis and absorption of complex carbohydrates		150-300	3 (with meals)	Transient gastrointestinal disturbances	
Acarbose			150-300	3 (with meals)		
Miglitol						
Thiazolidinedione	Peripheral insulin sensitizer				Upper respiratory tract infection, headache, edema, weight gain	
Rosiglitazone			4-8	1 or divided		
Pioglitazone			15-45	1		
Sitagliptin	GLP-1 receptor agonist	24	50-100	1	Upper respiratory tract infection, sore throat, diarrhea	No data in children or adolescents

From Jacobson-Dickman E, Levistky L: Oral agents in managing diabetes mellitus in children and adolescents, Pediatr Clin North Am *52:1689–1703, 2005.*

cells. They are occasionally used when metformin monotherapy is unsuccessful or contraindicated for some reason (use in certain forms of neonatal diabetes is discussed in the section on neonatal diabetes). Thiazolidinediones are not approved for use in pediatrics. Pramlintide (Symlin) is an analog of IAPP (islet amyloid polypeptide), which is a peptide that is cosecreted with insulin by the β cells and acts to delay gastric emptying, suppress glucagon, and possibly suppress food intake. It is not yet approved for pediatric use. Incretins are gut-derived peptides like GLP-1, GLP-2, and GIP (glucose-dependent insulinotropic peptide, previously known as gastric inhibitory protein) that are secreted in response to meals and act to enhance insulin secretion and action, suppress glucagon production, and delay gastric emptying (among other actions). GLP-1 analogs (e.g., exenatide) and agents that prolong endogenous GLP-1 action (e.g., sitagliptin) are now available for use in adults but are not yet approved for use in children; they may be associated with side effects such as hepatic injury and pancreatitis.

COMPLICATIONS

In the SEARCH study of diabetes in youth, 92% of the patients with T2DM had 2 or more elements of the metabolic syndrome (hypertension, hypertriglyceridemia, decreased high-density lipoprotein, increased waist circumference), including 70% with hypertension. In addition, the incidence of microalbuminuria and diabetic retinopathy appears to be higher in T2DM than it is in T1DM. In the SEARCH study, the incidence of microalbuminuria among patients who had T2DM of less than 5 yr duration was 7-22%, while retinopathy was present in 18.3%. Thus, all adolescents with T2DM should be screened for hypertension and lipid abnormalities and screening for microalbuminuria and retinopathy may be indicated even earlier than it is in T1DM. Sleep apnea and fatty liver disease are being diagnosed with increasing frequency and may necessitate referral to the appropriate specialists. Complications associated with all forms of diabetes and recommendations for screening are noted in Table 589-12; Table 589-15 lists additional conditions particularly associated with T2DM.

PREVENTION

The difficulties in achieving good glucose control and preventing diabetes complications make prevention a compelling strategy. This is particularly true for T2DM, which is clearly linked to modifiable risk factors (obesity, a sedentary lifestyle). The Diabetes Prevention Program was designed to prevent or delay the development of T2DM in adult individuals at high risk by virtue of IGT. The Diabetes Prevention Program results demonstrated that intensified lifestyle or drug intervention in individuals with IGT prevented or delayed the onset of T2DM. The results were striking. Lifestyle intervention reduced the diabetes incidence by 58%; metformin reduced the incidence by 31% compared with placebo. The effects were similar for men and women and for all racial and ethnic groups. Lifestyle interventions are believed to have similar beneficial effects in obese adolescents with IGT. Screening is indicated for at-risk patients (see Table 589-13).

Table 589-15 Monitoring for Complications and Comorbidities

CONDITION	SCREENING TEST	COMMENT
Hypertension	Blood pressure	
Fatty liver	Aspartate aminotransferase, alanine aminotransferase, possibly liver ultrasound	
Polycystic ovary syndrome	Menstrual history, assessment for androgen excess with free/total testosterone, dehydroepiandrosterone	
Microalbuminuria	Urine albumin concentration and albumin : creatinine ratios	
Dyslipidemia	Fasting lipid profile (total, low-density lipoprotein, high-density lipoprotein cholesterol, triglycerides)	Obtain at diagnosis and every 2 yr
Sleep apnea	Sleep study to assess overnight oxygen saturation

589.4 Other Specific Types of Diabetes

Britta M. Svoren and Nicholas Jospe

Most cases of diabetes in children as well as adults fall into the 2 broad categories of type 1 and type 2 diabetes, but up to 4% of cases are caused by single-gene disorders. These disorders include hereditary defects of β-cell function and insulin action, as well as rare forms of mitochondrial diabetes.

GENETIC DEFECTS OF β-CELL FUNCTION

Maturity-Onset Diabetes of Youth

Several forms of diabetes are associated with monogenic defects in β-cell function. Before these genetic defects were identified, this subset of diabetics was diagnosed on clinical grounds and described by the term MODY. This subtype of DM consists of a group of heterogeneous clinical entities that are characterized by onset before 25 yr, autosomal dominant inheritance, and a primary defect in insulin secretion. Strict criteria for the diagnosis of MODY include diabetes in at least 3 generations with autosomal dominant transmission and diagnosis before age 25 yr in at least 1 affected subject. Mutations have been found in at least in 10 different genes, accounting for the dominantly inherited monogenic defects of insulin secretion, for which the term MODY is used. The American Diabetes Association groups these disorders together under the broader category of “genetic defects of β-cell function.” Eleven of these defects typically meet the clinical criteria for the diagnosis of MODY and are listed in Table 589-16. Just 3 of them (MODY2 and MODY3 and MODY5) account for 90% of the cases in this category in European populations, but the distribution may be different in other ethnic groups. Except for MODY2 (which is caused by mutations in the enzyme glucokinase), all other forms are caused by genetic defects in various transcription factors (Table 589-16).

MODY2

This is the second most common form of MODY and accounts for approximately 15-30% of all patients diagnosed with MODY. Glucokinase plays an essential role in β-cell glucose sensing and heterozygous mutations in this gene lead to mild reductions in pancreatic β-cell response to glucose. Homozygotes with the same mutations are completely unable to secrete insulin in response to glucose and develop a form of permanent neonatal diabetes. Patients with heterozygous mutations have a higher threshold for insulin release but are able to secrete insulin adequately once blood glucose rises above 7 mmol/L. This results in a relatively mild form of diabetes (HbA_{1c} is usually less than 7%), with mild fasting hyperglycemia and IGT in the majority of patients. MODY2 may be misdiagnosed as type 1 diabetes in children, gestational diabetes in pregnant women, or well-controlled type 2 diabetes in adults (Table 589-17). An accurate diagnosis is important because most cases are not progressive, and except for gestational diabetes, may not require treatment. When needed, they can usually be treated with small doses of exogenously administered insulin. Treatment with oral agents (sulfonylureas and related drugs) can be successful and may be more acceptable to many patients.

MODY3

Patients affected with mutations in the transcription factor hepatocyte nuclear factor-1α show abnormalities of carbohydrate metabolism varying from IGT to severe diabetes and often progressing from a mild to a severe form over time. They are also prone to the development of vascular complications. This is the most common MODY subtype and accounts for 50-65% of all cases. These patients are very sensitive to the action of sulfonylureas and can usually be treated with relatively low doses of these oral agents, at least in the early stages of the disease. In children, this form of MODY is sometimes misclassified as T1DM and treated with insulin. Evaluation of autoimmune markers will rule out T1DM, and genetic testing for this form of MODY is now available and is indicated in patients with relatively mild diabetes and a family history suggestive of autosomal dominant inheritance. On the other hand, even patients with relatively mild and gradual onset of diabetes may have T1DM, and in the absence of a family history suggestive of autosomal dominant inheritance, the diagnosis of MODY is not warranted. Accurate diagnosis can lead to avoidance of unnecessary insulin treatment and specific genetic counseling.

Hepatocyte nuclear factor-4α (MODY1), insulin promoter factor (IPF)-1, also known as (PDX-1) (MODY4), hepatocyte nuclear factor 1β/TCF2 (MODY5), and NeuroD1 (MODY6) are all transcription factors that are involved in β-cell development and function and mutations in these lead to various rare forms of MODY. In addition to diabetes they can also have specific findings unrelated to hyperglycemia; for example, MODY1 is associated with low triglyceride and lipoprotein levels and MODY5 is associated with renal cysts and renal dysfunction. In terms of treatment, MODY1 and MODY4 may respond to oral sulfonylureas, but MODY5 does not respond to oral agents and requires treatment with insulin. NeuroD1 defects are extremely rare and not much is known about their natural history.

Primary or secondary defects in the glucose transporter-2, which is an insulin-independent glucose transporter, may also be associated with diabetes. Diabetes may also be a manifestation of a polymorphism in the glycogen synthase gene. This enzyme is crucially important for storage of glucose as glycogen in muscle. Patients with this defect are notable for marked insulin resistance and hypertension, as well as a strong family history of diabetes.

Mitochondrial Gene Defects

Maternally Inherited Diabetes and Deafness. Point mutations in mitochondrial DNA are sometimes associated with maternally inherited DM and deafness. The most common mitochondrial DNA mutation in these cases is the point mutation m.3243A>G in the transfer RNA leucine gene. This mutation is identical to the

Table 589-16 Summary of MODY Types and Special Clinical Characteristics

	GENE MUTATED	FUNCTION	SPECIAL FEATURE
MODY1	*HNF4α*	Transcription factor	Decreased levels of triglycerides, apolipoproteins AII and CIII (5-10% of MODY), neonatal hypoglycemia, very sensitive to sulfonylureas
MODY2	Glucokinase *(GCK)*	Enzyme, glucose sensor	Hyperglycemia of early onset but mild and nonprogressive; common (30-70% MODY)
MODY3	*HNF1α*	Transcription factor	Decreased renal absorption of glucose and consequent glycosuria; common (30-70% of cases of MODY); very sensitive to sulfonylureas
MODY4	*IPF-1*	Necessary for pancreatic development	Homozygous mutation causes pancreatic agenesis
MODY5	*HNF1β*	Transcription factor	Renal malformations; associated with uterine abnormalities, hypospadias, joint laxity, and learning difficulties, pancreatic atrophy, pancreatic exocrine insufficiency; 5-10% of MODY
MODY6	*NEUROD1*	Differentiation factor in the development of pancreatic islets	Extremely rare
MODY7	*KFL11*	Zinc finger transcription factor	Early-onset type II diabetes mellitus
MODY8	*CEL*	Bile salt–dependent lipase	Hyperglycemia; fecal elastase deficiency; exocrine pancreatic atrophy
MODY9	*PAX4*	Transcription factor	
MODY10	*INS*	Insulin gene	Usually associated with neonatal diabetes
MODY11	*BLK*	B-lymphocyte tyrosine kinase	Early-onset T1DM without autoantibodies

MODY, maturity-onset diabetes of the young.

mutation in MELAS (myopathy, encephalopathy, lactic acidosis, and stroke-like syndrome), but this syndrome is not associated with diabetes; the phenotypic expression of the same defect varies. Diabetes in most of these cases presents insidiously but approximately 20% of patients have an acute presentation resembling T1DM. The mean age of diagnosis of diabetes is 37 yr but cases have been reported as young as 11 yr. This mutation has been estimated to be present in 1.5% of Japanese diabetics, which may be higher than the prevalence in other ethnic groups. Metformin should be avoided in these patients because of the theoretical risk of severe lactic acidosis in the presence of mitochondrial dysfunction.

Another form of IDDM, sometimes associated with mitochondrial mutations, is the **Wolfram syndrome**. **Wolfram syndrome 1** is characterized by diabetes insipidus, DM, optic atrophy, and deafness—thus, the acronym DIDMOAD. Some patients with diabetes appear to have severe insulinopenia, whereas others have significant insulin secretion as judged by C-peptide. The overall prevalence is 1 in 770,000 live births. The sequence of appearance of the stigmata is as follows: nonautoimmune IDDM in the 1st decade, central diabetes insipidus and sensorineural deafness in two thirds to three fourths of the patients in the 2nd decade, renal tract anomalies in about one half of the patients in the 3rd decade, and neurologic complications such as cerebellar ataxia and myoclonus in one half to two thirds of the patients in the 4th decade. Other features include primary gonadal atrophy in the majority of males and a progressive neurodegenerative course with neurorespiratory death at a median age of 30 yr. Some (but not all) cases are caused by mutations in the *WFS-1* (wolframin) gene on chromosome 4p. **Wolfram syndrome 2** has early-onset optic atrophy, DM, deafness, and a shortened life span but no diabetes insipidus; the associated gene is *CISD2*.

DIABETES MELLITUS OF THE NEWBORN

Neonatal DM is exceedingly rare. Onset of classic autoimmune T1DM before the age of 6 mo is most unusual and most cases of diabetes in this age range are caused by genetic mutations.

Transient Neonatal Diabetes Mellitus

Neonatal diabetes is transient in approximately 50% of cases, but after an interim period of normal glucose tolerance, 50-60% of these patients develop permanent diabetes (at an average age of 14 yr). There are also reports of patients with classic T1DM who formerly had transient diabetes of the newborn. It remains to be determined whether this association of transient diabetes in the newborn followed much later in life by classic T1DM is a chance occurrence or causally related.

The syndrome of transient DM in the newborn infant has its onset in the 1st wk of life and persists several weeks to months before spontaneous resolution. Median duration is 12 wk. It occurs most often in infants who are small for gestational age and is characterized by hyperglycemia and pronounced glycosuria, resulting in severe dehydration and, at times, metabolic acidosis, but with only minimal or no ketonemia or ketonuria. There may also be findings such as umbilical hernia or large tongue. Insulin responses to glucose or tolbutamide are low to absent; basal plasma insulin concentrations are normal. After spontaneous recovery, the insulin responses to these same stimuli are brisk and normal, implying a functional delay in β-cell maturation with spontaneous resolution. Occurrence of the syndrome in consecutive siblings has been reported. About 70% of cases are due to a**bnormalities of an imprinted locus on chromosome 6q24,** resulting in overexpression of paternally expressed genes such as pleomorphic adenoma gene–like 1 (PLAGL1/ZAC) and hydatidiform mole associated and imprinted (HYMAI). Most of the remaining cases are caused by mutations in K_{ATP} channels. Mutations in K_{ATP} channels also cause many cases of permanent neonatal diabetes, but there is practically no overlap between the mutations that lead to transient neonatal DM and those causing permanent neonatal DM. This syndrome of transient neonatal DM should be distinguished from the severe hyperglycemia that may occur in hypertonic dehydration; that usually occurs in infants beyond the newborn period and responds promptly to rehydration with minimal or no requirement for insulin.

Administration of insulin is mandatory during the active phase of DM in the newborn. One to 2 units/kg/24 hr of an intermediate-acting insulin in 2 divided doses usually results in dramatic improvement and accelerated growth and gain in weight. Attempts at gradually reducing the dose of insulin may be made as soon as recurrent hypoglycemia becomes manifested or after 2 mo of age. Genetic testing is now available for 6q24 abnormalities as well as potassium channel defects and should be obtained on all patients and recurrence risk assessment by a genetic counselor is recommended.

Permanent Neonatal Diabetes Mellitus

Permanent DM in the newborn period is caused in approximately 50% of the cases by mutations in the *KCNJ11* (potassium inwardly-rectifying channel J, member 11) and *ABCC8* (adenosine triphosphate–binding cassette, subfamily C, member 8) genes. These genes code for the Kir6.2 and SUR1 subunits of the adenosine triphosphate–sensitive potassium channel, which is involved in an essential step in insulin secretion by the β cell. Some cases are caused by pancreatic agenesis as a result of homozygous mutations in the *IPF-1* gene (where heterozygous mutations cause MODY4); homozygous mutations in the glucokinase gene (where heterozygous mutations cause MODY2); and mutations in the insulin gene. Almost all these infants are small at birth because of the role of insulin as an intrauterine growth factor. Instances of affected twins and families with more than 1 affected infant have been reported. Infants with permanent neonatal DM may be initially euglycemic and typically present between birth and 6 mo of life (mean age of presentation is 5 wk). There is a spectrum of severity and up to 20% have neurologic features. The most severely affected patients have the syndrome of *d*evelopmental delay, *e*pilepsy and *n*eonatal *d*iabetes (DEND syndrome). Less-severe forms of DEND are labeled intermediate DEND or i-DEND.

Activating mutations in the *KCNJ11* gene (encoding the adenosine triphosphate–sensitive potassium channel subunit Kir6.2) are associated with both transient neonatal DM and permanent neonatal DM, with particular mutations being associated with each phenotype. More than 90% of these patients respond to sulfonylureas (at higher doses than those used in T2DM), but patients with severe neurologic disease may be less responsive. Mutations in the *ABCC8* gene (encoding the SUR1 subunit of this potassium channel) were thought to be less likely to respond to sulfonylureas (because this is the subunit that binds sulfonylurea drugs), but some of these mutations are reported to respond and patients have been successfully switched from insulin to oral therapy. Several protocols for switching the patient from insulin to glibenclamide are available and patients are usually stabilized on doses ranging from 0.4-1 mg/kg/day. Because approximately 50% of neonatal diabetics have K-channel mutations that can be switched to sulfonylurea therapy, with dramatic improvement in glycemic control and quality of life, *all* patients with diabetes diagnosed before 6 mo of age (and perhaps even those diagnosed before 12 mo of age) should now be screened for these mutations by genetic testing.

IPEX Syndrome

IPEX means immunodysregulation, polyendocrinopathy, and enteropathy, X-linked. In most patients with IPEX, mutations in the *FOXP3* (Forkhead box P3) gene, a specific marker of natural and adaptive regulatory T cells, leads to severe immune dysregulation and rampant autoimmunity. Autoimmune diabetes develops in >90% of cases, usually within the 1st few wk of life and is accompanied by enteropathy, failure to thrive, and other autoimmune disorders (see Chapter 126.5).

Abnormalities of the Insulin Gene

Diabetes of variable degrees may also result from defects in the insulin gene that lead to various amino acid substitutions that impair the effectiveness of insulin at the receptor level. Insulin gene defects are exceedingly rare and may be associated with relatively mild diabetes or even normal glucose tolerance. Diabetes may also develop in patients with faulty processing of proinsulin to insulin (an autosomal dominant defect). These defects are notable for the high concentration of insulin as measured by radioimmunoassay, whereas MODY and glucose transporter-2 defects are characterized by relative or absolute deficiency of insulin secretion for the prevailing glucose concentrations.

GENETIC DEFECTS OF INSULIN ACTION

Various genetic mutations in the insulin receptor can impair the action of insulin at the insulin receptor or impair postreceptor signaling, leading to insulin resistance.

The mildest form of the syndrome with mutations in the insulin receptor was previously known as *type A insulin resistance*. This is associated with hirsutism, hyperandrogenism, and cystic ovaries in females, without obesity. Acanthosis nigricans may be present and life expectancy is not significantly impaired. More-severe forms of insulin resistance are seen in 2 mutations in the insulin receptor gene that cause the pediatric syndromes of Donohue syndrome (formerly called leprechaunism) and Rabson-Mendenhall syndrome.

Donohue Syndrome

This is a syndrome characterized by intrauterine growth restriction, fasting hypoglycemia, and postprandial hyperglycemia in association with profound resistance to insulin; severe hyperinsulinemia is seen compared to age-matched infants during an oral glucose tolerance test. Various defects of the insulin receptor have been described, thereby attesting to the important role of insulin and its receptor in fetal growth and possibly in morphogenesis. Most of these patients die in the 1st yr of life.

Rabson-Mendenhall Syndrome

This entity is defined by clinical manifestations that appear to be intermediate between those of acanthosis nigricans with insulin resistance type A and Donohue syndrome. The features include extreme insulin

Table 589-18 Clinical and Biochemical Features of Inherited Lipodystrophies

	CONGENITAL GENERALIZED LIPODYSTROPHY		FAMILIAL PARTIAL LIPODYSTROPHY	
Subtype	**BSCL1**	**BSCL2**	**FPLD2**	**FPLD3**
Defective gene	*AGPAT2*	*BSCL2*	*LMNA*	*PPARG*
Clinical onset	Soon after birth	Soon after birth	Puberty	Usually puberty, but may present in younger children
Fat distribution	Generalized absence	Generalized absence	Loss of limb and gluteal fat; typically excess facial and nuchal fat; trunk fat often lost	Loss of limb and gluteal fat; preserved facial and trunk fat
Cutaneous features	Acanthosis nigricans and skin tags; hirsutism common in women	Acanthosis nigricans and skin tags; hirsutism common in women	Acanthosis nigricans and skin tags; hirsutism common in women	Acanthosis nigricans and skin tags; hirsutism common in women
Musculoskeletal	Acromegaloid features common	Acromegaloid features common	Frequent muscle hypertrophy; some have overlap features of muscular dystrophy	Nil specific
Nonalcoholic fatty liver disease	Severe	Severe	Yes	Yes
Dyslipidemia	Severe associated with pancreatitis	Severe associated with pancreatitis	Yes, may be severe	Yes, may be severe
Insulin resistance	Severe early onset	Severe early onset	Severe	Severe; early onset in some
Diabetes onset	<20 yr	<20 yr	Variable; generally later in men than women	Variable; generally later in men than women
Hypertension	Common	Common	Common	Very common
Other		Mild mental retardation possible		

From Semple RK, Savage DB, Halsall DJ, O'Rahilly S: Syndromes of severe insulin resistance and/or lipodystrophy. In Weiss RE, Refetoff S, editors: Genetic diagnosis of endocrine disorders, *Philadelphia, 2010, Elsevier, Table 4.2.*

resistance, acanthosis nigricans, abnormalities of the teeth and nails, and pineal hyperplasia. It is not clear whether this syndrome is entirely distinct from Donohue syndrome; however, by comparison, patients with Rabson-Mendenhall tend to live significantly longer. Therapies with modest benefit have included insulin-like growth factor-1 and leptin.

Lipoatrophic Diabetes

Various forms of lipodystrophy are associated with insulin resistance and diabetes (Table 589-18). Familial partial lipoatrophy is associated with mutations in the *LMNA* gene, encoding nuclear envelope proteins lamin A and C. Severe generalized lipoatrophy is associated with mutations in the seipin and *AGPAT2* genes, but the mechanism by which these mutations lead to insulin resistance and diabetes is not known.

Stiff-Person Syndrome

This is an extremely rare autoimmune central nervous system disorder that is characterized by progressive stiffness and painful spasms of the axial muscles and very high titers of glutamic acid decarboxylase antibodies. About one third of the patients also develop T1DM.

Systemic Lupus Erythematosus

In rare cases, patients with systemic lupus erythematosus may develop autoantibodies to the insulin receptor, leading to insulin resistance and diabetes.

CYSTIC FIBROSIS–RELATED DIABETES

See Chapter 403.

As patients with cystic fibrosis (CF) live longer, an increasing number are being diagnosed with cystic fibrosis–related diabetes (CFRD). Females appear to have a somewhat higher risk of CFRD than males and prevalence increases with increasing age until age 40 yr (there is a decline in prevalence after that, presumably because only the healthiest CF patients survive beyond that age). There is an association with pancreatic insufficiency and there may be a higher risk in patients with class I and class II CF transmembrane conductance regulator mutations. A large multicenter study in the United States reported prevalence (in all ages) of 17% in females and 12% in males. Cross-sectional studies indicate that the prevalence of IGT may be significantly higher than this and up to 65% of children with CF have diminished 1st phase insulin secretion, even when they have normal glucose tolerance. In Denmark, oral glucose tolerance screening of the entire CF population demonstrated no diabetes in patients younger than 10 yr, diabetes in 12% of patients age 10-19 yr, and diabetes in 48% of adults age 20 yr and older. At a Midwestern center where routine annual oral glucose tolerance screening is performed, only about one half of children and one fourth of adults have normal glucose tolerance.

Patients with CFRD have features of both T1DM and T2DM. In the pancreas, exocrine tissue is replaced by fibrosis and fat and many of the pancreatic islets are destroyed. The remaining islets demonstrate diminished numbers of β-, α-, and pancreatic polypeptide-secreting cells. Secretion of the islet hormones insulin, glucagon, and pancreatic polypeptide is impaired in patients with CF in response to a variety of secretagogs. This pancreatic damage leads to slowly progressive insulin deficiency, of which the earliest manifestation is an impaired 1st phase insulin response. As patients age, this response becomes progressively delayed and less robust than normal. At the same time, these patients develop insulin resistance due to chronic inflammation and the intermittent use of corticosteroids. Insulin deficiency and insulin resistance lead to a very gradual onset of IGT that eventually evolves into diabetes. In some cases, diabetes may wax and wane with disease exacerbations and the use of corticosteroids. The clinical presentation is similar to that of T2DM in that the onset of the disease is insidious and the occurrence of ketoacidosis is rare. Islet antibody titers are negative. Microvascular complications do develop but may do so at a slower rate than in typical T1DM or T2DM. Macrovascular complications do not appear to be of concern in CFRD, perhaps because of the shortened

life span of these patients. Several factors unique to CF influence the onset and the course of diabetes. For example: (1) frequent infections are associated with waxing and waning of insulin resistance; (2) energy needs are increased because of infection and pulmonary disease; (3) malabsorption is common, despite enzyme supplementation; (4) nutrient absorption is altered by abnormal intestinal transit time; (5) liver disease is frequently present; (6) anorexia and nausea are common; (7) there is a wide variation in daily food intake based on the patient's acute health status; and (8) both insulin and glucagon secretion are impaired (in contrast to autoimmune diabetes, in which only insulin secretion is affected).

Impaired glucose tolerance and CFRD are associated with poor weight gain and there is evidence that treatment with insulin improves weight gain and slows the rate of pulmonary deterioration. Because of these observations, the CF Foundation recommends routine diabetes screening of all children with CF, starting at age 12 yr. Despite debate over the ideal screening modality, the current recommendation is the 2 hr glucose tolerance test, though it is possible that simply obtaining a single 2 hr postprandial glucose value may be sufficient. When hyperglycemia develops, the accompanying metabolic derangements are usually mild, and relatively low doses of insulin usually suffice for adequate management. Basal insulin may be started initially, but basal-bolus therapy similar to that used in T1DM will eventually be needed. Dietary restrictions are minimal as increased energy needs are present and weight gain is usually desired. Ketoacidosis is very uncommon but may occur with progressive deterioration of islet cell function. Impaired glucose tolerance is not necessarily an indication for treatment, but patients who have poor growth and inadequate weight gain may benefit from the addition of basal insulin even if they do not meet the criteria for diagnosis of diabetes.

AUTOIMMUNE DISEASES

Chronic lymphocytic thyroiditis (Hashimoto thyroiditis) is frequently associated with T1DM in children (see Chapter 566). As many as 1 in 5 insulin-dependent diabetic patients have thyroid antibodies in their serum; the prevalence is 2-20 times greater than in control populations. Only a small proportion of these patients, however, acquire clinical hypothyroidism; the interval between diagnosis of diabetes and thyroid disease averages about 5 yr. Periodic palpation of the thyroid gland is indicated in all diabetic children; if the gland feels firm or enlarged, serum measurements of thyroid antibodies and TSH should be obtained. A confirmed TSH level of greater than 10 μU/mL indicates existing or incipient thyroid dysfunction that warrants replacement with thyroid hormone. Deceleration in the rate of growth may also be caused by thyroid failure and is, in itself, a reason for securing serum measurements of thyroxine and TSH concentrations.

When diabetes and thyroid disease coexist, the possibility of autoimmune adrenal insufficiency should be considered. It may be heralded by decreasing insulin requirements, increasing pigmentation of the skin and buccal mucosa, salt craving, weakness, asthenia and postural hypotension, or even frank Addisonian crisis. This syndrome is most unusual in the 1st decade of life, but it may become apparent in the 2nd decade or later.

Celiac disease, which is caused by hypersensitivity to dietary gluten, is another autoimmune disorder that occurs with significant frequency in children with T1DM (see Chapter 338.2). It is estimated that approximately 7-15% of children with T1DM develop celiac disease within the 1st 6 yr of diagnosis, and the incidence of celiac disease is significantly higher in children younger than 4 yr of age and in girls. Young children with T1DM and celiac disease usually present with gastrointestinal symptoms (abdominal cramping, diarrhea, and gastroesophageal reflux), growth failure as a consequence of suboptimal weight gain, and unexplained hypoglycemic reactions because of nutrient malabsorption, including vitamin D; adolescents may remain asymptomatic. The diagnosis of celiac disease is considered if serum tissue transglutaminase antibody titers are elevated in the presence of normal serum total IgA levels. The diagnosis is confirmed on endoscopic evaluation and biopsy of small bowel revealing characteristic atrophy of intestinal villi. Therapy consists of a gluten-free diet, which will alleviate gastrointestinal symptoms and may reduce glycemic excursions.

Circulating antibodies to gastric parietal cells and to intrinsic factor are 2-3 times more common in patients with T1DM than in control subjects. The presence of antibodies to gastric parietal cells is correlated with atrophic gastritis and antibodies to intrinsic factor are associated with malabsorption of vitamin B_{12}. However, megaloblastic anemia is rare in children with T1DM.

A variant of the multiple endocrine deficiency syndrome is characterized by T1DM, idiopathic intestinal mucosal atrophy with associated inflammation and severe malabsorption, IgA deficiency, and circulating antibodies to multiple endocrine organs including the thyroid, adrenal, pancreas, parathyroid, and gonads. In addition, nondiabetic family members have an increased frequency of vitiligo, Graves disease, and multiple sclerosis as well as low complement levels and antibodies to endocrine tissues.

ENDOCRINOPATHIES

The endocrinopathies listed in Table 589-1 are only rarely encountered as a cause of diabetes in childhood. They may accelerate the manifestations of diabetes in those with inherited or acquired defects in insulin secretion or action.

DRUGS

High-dose oral or parenteral steroid therapy usually results in significant insulin resistance leading to glucose intolerance and overt diabetes. The immunosuppressive agents cyclosporin and tacrolimus are toxic to β cells, causing IDDM in a significant proportion of patients treated with these agents. Their toxicity to pancreatic β cells was 1 of the factors that limited their usefulness in arresting ongoing autoimmune destruction of β cells. Streptozotocin and the rodenticide Vacor are also toxic to β cells, causing diabetes.

There are no consensus guidelines regarding treatment of steroid-induced hyperglycemia in children. Many patients on high-dose steroids have elevated blood glucose during the day and evening, but become normoglycemic late at night and early in the morning. In general, significant hyperglycemia in an inpatient setting is treated with short-acting insulin on an as-needed basis. Basal insulin may be added when fasting hyperglycemia is significant. Outpatient treatment can be more difficult, but when treatment is needed, protocols similar to the basal-bolus regimens used in T1DM are used.

GENETIC SYNDROMES ASSOCIATED WITH DIABETES MELLITUS

A number of rare genetic syndromes associated with IDDM or carbohydrate intolerance have been described (see Table 589-1). These syndromes represent a broad spectrum of diseases, ranging from premature cellular aging, as in the Werner and Cockayne syndromes (see Chapter 90) to excessive obesity associated with hyperinsulinism, resistance to insulin action, and carbohydrate intolerance, as in the Prader-Willi syndrome (see Chapters 80 and 81). Some of these syndromes are characterized by primary disturbances in the insulin receptor or in antibodies to the insulin receptor without any impairment in insulin secretion. Although rare, these syndromes provide unique models to understand the multiple causes of disturbed carbohydrate metabolism from defective insulin secretion or from defective insulin action at the cell receptor or postreceptor level.

The Nervous System

PART XXVII

Chapter 590

Neurologic Evaluation

Rebecca K. Lehman and Nina F. Schor

HISTORY

A detailed history is the cornerstone of any neurologic assessment. Although parents may be the primary informants, most children older than 3-4 yr are capable of contributing to their history and should be questioned directly.

The history should begin with the chief complaint, as well as a determination of the complaint's relative significance within the context of normal development (see Chapters 9-16). The latter step is critical because a 13 mo old who cannot walk may be perfectly normal, whereas a 4 yr old who cannot walk might have a serious neurologic condition.

Next, the history of present illness should provide a chronological outline of the patient's symptoms, with attention paid to location, quality, intensity, duration, associated features, and alleviating or exacerbating factors. It is essential to perform a review of systems, because abnormalities of the central nervous system (CNS) often manifest with vague, nonfocal symptoms that may be misattributed to other organ systems (e.g., vomiting, constipation, urinary incontinence). A detailed history might suggest that vomiting is as a result of increased intracranial pressure (ICP) rather than gastritis or that constipation and urinary incontinence are caused by a spinal cord tumor rather than behavioral stool withholding. In addition, a systemic illness may produce CNS manifestations such as lupus erythematosus (seizures, psychosis, demyelination) or mitochondrial disorders (developmental delay, strokes, hypotonia).

Following the chief complaint and history of present illness, the physician should obtain a complete birth history, particularly if a congenital disorder is suspected. The birth history should begin with a review of the pregnancy, including specific questions about common complications, such as pregnancy-induced hypertension, preeclampsia, gestational diabetes, vaginal bleeding, infections, and falls. It is important to quantify any cigarette, alcohol, or drug (prescription, herbal, illicit) use. Inquiring about fetal movement might provide clues to an underlying diagnosis, because decreased or absent fetal activity can be associated with chromosomal anomalies and CNS or neuromuscular disorders. Finally, any abnormal ultrasound or amniocentesis results should be noted.

A labor history should address the gestational age at delivery and mode of delivery (spontaneous vaginal, vacuum- or forceps-assisted, cesarean section) and should comment on the presence or absence of fetal distress. If delivery was by cesarean section, it is essential to record the indication for surgery.

The birth weight, length, and head circumference provide useful information about the duration of a given problem, as well as insights into the uterine environment. Parents can usually provide a reliable history of their child's postnatal course; however, if the patient was resuscitated or had a complicated hospital stay, it is often helpful to obtain the hospital records. The physician should inquire about the infant's general well-being, feeding and sleeping patterns, activity level, and the nature of the infant's cry. If the infant had jaundice, it is important to determine both the degree of jaundice and how it was managed. Historical markers of neurologic dysfunction include full-term infants who are unable to breathe spontaneously; have poor, uncoordinated sucks; need an inordinate amount of time to feed; or require gavage feeding. Again, it is important to consider the developmental context, because all of these issues would be expected in premature infants, particularly those with a very-low birthweight. Double-checking the state newborn screening results may provide a clue to abnormal neurologic manifestation in an infant.

The most important component of a neurologic history is the **developmental assessment** (see Chapters 9-14 and 16). Careful evaluation of a child's social, cognitive, language, fine motor, and gross motor skills is required to distinguish normal development from either isolated or global (i.e., in 2 or more domains) developmental delay. An abnormality in development from birth suggests an intrauterine or perinatal cause, but a loss of skills **(regression)** over time strongly suggests an underlying degenerative disease of the CNS, such as an inborn error of metabolism. The ability of parents to recall the precise timing of their child's developmental milestones is extremely variable. It is often helpful to request old photographs of the child or to review the baby book, where the milestones may have been dutifully recorded. In general, parents are aware when their child has a developmental problem, and the physician should show appropriate concern. Table 590-1 outlines the upper limits of normal for attaining specific developmental milestones. Chapter 16 includes a comprehensive review of developmental screening tests and their interpretation.

Family history is extremely important in the neurologic evaluation of a child. Most parents are extremely cooperative in securing medical information about family members, particularly if it might have relevance for their child. The history should document the age and history of neurologic disease, including developmental delay, epilepsy, migraine, stroke, and inherited disorders, for all 1st- and 2nd-degree relatives. It is important to inquire directly about miscarriages or fetal deaths in utero and to document the sex of the embryo or fetus, as well as the gestational age at the time of demise. When available, the results of postmortem examinations should be obtained, as they can have a direct bearing on the patient's condition. The parents should be questioned about their ethnic backgrounds, because some genetic disorders occur more commonly within specific populations (e.g., Tay-Sachs disease in the Ashkenazi Jewish population). They should also be asked if there is any chance that they could be related to each other, because the incidence of metabolic and degenerative disorders of the CNS is increased significantly in children of **consanguineous** marriages.

The social history should detail the child's current living environment, as well as the child's relationship with other family members. It is important to inquire about recent stressors, such as divorce, remarriage, birth of a sibling, or death of a loved one, because they can affect the child's behavior. If the child is in daycare or school, one should document the child's academic and social performance, paying particular attention to any abrupt changes. Academic performance can be assessed by asking about the child's latest report card, and peer relationships can be evaluated by having the child name his or her "best friends." Any child who is unable to name at least 2 or 3 playmates might have abnormal social development. In some cases, discussions with the daycare worker or teacher provide useful ancillary data.

NEUROLOGIC EXAMINATION

The neurologic examination begins at the outset of the interview. Indirect observation of the child's appearance and movements can yield valuable information about the presence of an underlying disorder. For instance, it may be obvious that the child has dysmorphic facies, an

Table 590-1 Screening Scheme for Developmental Delay: Upper Range

AGE (mo)	GROSS MOTOR	FINE MOTOR	SOCIAL SKILLS	LANGUAGE
3	Supports weight on forearms	Opens hands spontaneously	Smiles appropriately	Coos, laughs
6	Sits momentarily	Transfers objects	Shows likes and dislikes	Babbles
9	Pulls to stand	Pincer grasp	Plays pat-a-cake, peek-a-boo	Imitates sounds
12	Walks with 1 hand held	Releases an object on command	Comes when called	1-2 meaningful words
18	Walks upstairs with assistance	Feeds from a spoon	Mimics actions of others	At least 6 words
24	Runs	Builds a tower of 6 blocks	Plays with others	2-3–word sentences

unusual posture, or an abnormality of motor function manifested by a hemiparesis or gait disturbance. The child's behavior while playing and interacting with his or her parents may also be telling. A normal child usually plays independently early in the visit, but then engages in the interview process. A child with attention-deficit/hyperactivity disorder might display impulsive behavior in the examining room, and a child with neurologic impairment might exhibit complete lack of awareness of the environment. Finally, note should be made of any unusual odors about the patient, because some metabolic disorders produce characteristic scents (e.g., the "musty" smell of phenylketonuria or the "sweaty feet" smell of isovaleric acidemia). If such an odor is present, it is important to determine whether it is persistent or transient, occurring only with illnesses.

The examination should be conducted in a nonthreatening, child-friendly setting. The child should be allowed to sit where the child is most comfortable, whether it be on a parent's lap or on the floor of the examination room. The physician should approach the child slowly, reserving any invasive or painful tests (e.g., measurement of head circumference, gag reflex) for the end of the examination. In the end, the more that the examination seems like a game, the more the child will cooperate. Because the neurologic examination of an infant requires a somewhat modified approach from that of an older child, the 2 groups are considered separately (see Chapters 9, 10, and 94 vs Chapters 11-14).

Mental Status

Age aside, the neurologic examination should include an assessment of the patient's mental status in terms of both level of arousal and interaction with the environment. Premature infants born at <28 wk of gestation do not have consistent periods of alertness, whereas slightly older infants arouse from sleep with gentle physical stimulation. Sleep–wake patterns are well developed at term. Because the level of alertness of a neonate depends on many factors, including the time of the last feeding, room temperature, and gestational age, serial examinations are critical when evaluating for changes in neurologic function. Older children's mental status can be assessed by watching them play. Having them tell a story, draw a picture, or complete a puzzle can also be helpful in assessing cognitive function. Memory can be evaluated informally as patients recount their personal information, as well as more formally by asking them to register and recall 3 objects or perform a digit span.

Head

Correct measurement of the **head circumference** is important. It should be performed at every visit for patients younger than 3 yr and should be recorded on a suitable head growth chart. To measure, a nondistensible plastic measuring tape is placed over the mid-forehead and extended circumferentially to include the most prominent portion of the occiput. If the patient's head circumference is abnormal, it is important to document the head circumferences of the parents and siblings. Errors in the measurement of a newborn skull are common owing to scalp edema, overriding sutures, and the presence of cephalohematomas. The average rate of head growth in a healthy premature infant is 0.5 cm in the 1st 2 wk, 0.75 cm in the 3rd wk, and 1.0 cm in the 4th wk and every week thereafter until the 40th wk of development. The head circumference of an average term infant measures 34-35 cm at birth, 44 cm at 6 mo, and 47 cm at 1 yr of age (see Chapters 9 and 10).

Figure 590-1 Congenital hydrocephalus. Note the enlarged cranium and prominent scalp veins.

If the brain is not growing, the skull will not grow; therefore, a small head frequently reflects a small brain, or **microcephaly**. Conversely, a large head may be associated with a large brain, or **macrocephaly**, which is most commonly familial but may be from a disturbance of growth, neurocutaneous disorder (e.g., neurofibromatosis), chromosomal defect (e.g., Klinefelter syndrome), or storage disorder. Alternatively, the head size may be increased secondary to hydrocephalus (Fig. 590-1) or chronic subdural hemorrhages. In the latter case, the skull tends to assume a square or box-like shape, because the long-standing presence of fluid in the subdural space causes enlargement of the middle fossa.

The shape of the head should be documented carefully. Plagiocephaly, or flattening of the skull, can be seen in normal infants but may be particularly prominent in hypotonic or weak infants, who are less mobile. A variety of abnormal head shapes can be seen when cranial sutures fuse prematurely, as in the various forms of inherited **craniosynostosis** (see Chapter 591.12).

An infant has 2 **fontanels** at birth: a diamond-shaped anterior fontanel at the junction of the frontal and parietal bones that is open at birth, and a triangular posterior fontanel at the junction of the parietal and occipital bones that can admit the tip of a finger or may be closed at birth. If the posterior fontanel is open at birth, it should close over the ensuing 6-8 wk; its persistence suggests underlying hydrocephalus or congenital hypothyroidism. The anterior fontanel varies greatly in size, but it usually measures approximately 2×2 cm. The average time of closure is 18 mo, but the fontanel can close normally as early as 9 mo. A very small or absent anterior fontanel at birth might indicate craniosynostosis or microcephaly, whereas a very large fontanel can

signify a variety of problems. The fontanel is normally slightly depressed and pulsatile and is best evaluated by holding the infant upright while the infant is asleep or feeding. A bulging fontanel is a potential indicator of increased ICP, but vigorous crying can cause a protuberant fontanel in a normal infant.

Inspection of the head should include observation of the venous pattern, because increased ICP and thrombosis of the superior sagittal sinus can produce marked venous distention. Dysmorphic facial features can indicate a neurodevelopmental aberration. Likewise, cutaneous abnormalities, such as cutis aplasia or abnormal hair whorls, can suggest an underlying brain malformation or genetic disorder.

Palpation of a newborn's skull characteristically reveals **molding** of the skull accompanied by **overriding sutures**—a result of the pressures exerted on the skull during its descent through the pelvis. Marked overriding of the sutures beyond the early neonatal period is cause for alarm, because it suggests an underlying brain abnormality. Palpation additionally might reveal bony bridges between sutures **(craniosynostosis),** cranial defects, or, in premature infants, softening of the parietal bones **(craniotabes).**

Auscultation of the skull is an important adjunct to the neurologic examination. **Cranial bruits** may be noted over the anterior fontanel, temporal region, or orbits, and are best heard using the diaphragm of the stethoscope. Soft symmetric bruits may be discovered in normal children younger than 4 yr of age or in association with a febrile illness. Demonstration of a loud or localized bruit is usually significant and warrants further investigation, because they may be associated with severe anemia, increased ICP, or arteriovenous malformations of the middle cerebral artery or vein of Galen. It is important to exclude murmurs arising from the heart or great vessels, because they may be transmitted to the cranium.

Cranial Nerves

Olfactory Nerve (Cranial Nerve I)

Anosmia, loss of smell, most commonly occurs as a transient abnormality in association with an upper respiratory tract infection or allergies. Permanent causes of anosmia include head trauma with damage to the ethmoid bone or shearing of the olfactory nerve fibers as they cross the cribriform plate, tumors of the frontal lobe, intranasal drug use, and exposure to toxins (acrylates, methacrylates, cadmium). Occasionally, a child who recovers from purulent meningitis or develops hydrocephalus has a diminished sense of smell. Rarely, anosmia is congenital, in which case it can occur as an isolated deficit or as part of Kallmann syndrome, a familial disorder characterized by hypogonadotropic hypogonadism and congenital anosmia. Although not a routine component of the examination, smell can be tested reliably as early as the 32nd wk of gestation by presenting a stimulus and observing for an alerting response, withdrawal, or both. Care should be taken to use appropriate stimuli, such as coffee or peppermint, as opposed to strongly aromatic substances (e.g., ammonia inhalants) that stimulate the trigeminal nerve. Each nostril should be tested individually by pinching shut the opposite side.

Optic Nerve (Cranial Nerve II)

Assessment of the optic disc and retina is a critical component of the neurologic examination. Although the retina is best visualized by dilating the pupil, most physicians do not have ready access to mydriatic agents at the bedside; therefore, it may be necessary to consult an ophthalmologist in some cases. Mydriatics should not be administered to patients whose pupillary responses are being followed as a marker for impending herniation or to patients with cataracts. When mydriatics are used, both eyes should be dilated, because unilateral papillary fixation and dilation can cause confusion and worry in later examiners unaware of the pharmacologic intervention. Examination of an infant's retina may be facilitated by providing a nipple or soother and by turning the head to one side. The physician gently strokes the patient to maintain arousal, while examining the closer eye. An older child should be placed in the parent's lap and should be distracted by bright objects or toys. The color of the optic nerve is salmon-pink in a child but may be gray-white in a newborn, particularly if the newborn has fair coloring. This normal finding can cause confusion and can lead to the improper diagnosis of optic atrophy.

Disc edema refers to swelling of the optic disc, and **papilledema** specifically refers to swelling that is secondary to increased ICP. Papilledema rarely occurs in infancy because the skull sutures can separate to accommodate the expanding brain. In older children, papilledema may be graded according to the Frisen scale (Fig. 590-2). Disc edema must be differentiated from **papillitis**, or inflammation of the optic nerve. Both conditions manifest with enlargement of the blind spot, but visual acuity and color vision tend to be spared in early papilledema in contrast to what occurs in optic neuritis.

Retinal hemorrhages occur in 30-40% of all full-term newborn infants. The hemorrhages are more common after vaginal delivery than after Cesarean section and are not associated with birth injury or with neurologic complications. They disappear spontaneously by 1-2 wk of age. The presence of retinal hemorrhages beyond the early neonatal period should raise a concern for nonaccidental trauma.

Vision

At 28 wk of corrected gestational age, a premature infant blinks in response to a bright light, and at 32 wk, the infant maintains eye closure until the light source is removed. A normal 37 wk infant turns the head and eyes toward a soft light, and a term infant is able to fix on and follow a target, such as the examiner's face. **Optokinetic nystagmus** (OKN), which is conjugate nystagmus that occurs during attempted fixation on a series of rapidly moving objects, can also be used as a crude assessment of the visual system in infants. OKN is elicited by moving an OKN tape—usually a strip of material with alternating 2-inch black and white strips—across the patient's visual field. Although OKN responses can be tested monocularly in neonates, they do not become symmetric until 4-6 mo of age.

Visual fields can be tested in an infant or young child by advancing a brightly colored object from behind the patient's head into the peripheral visual field and noting when the patient first looks at the object. Suspension of the object by a string prevents the patient from focusing on the examiner's hand and arm. The examiner should be certain that the patient is responding to seeing, not hearing, the object.

Visual acuity in term infants approximates 20/150 and reaches the adult level of 20/20 by about 6 mo of age. Children who are too young to read the standard letters on a Snellen eye chart may learn the "E game," which entails pointing to indicate the direction that the E is facing. Children as young as 2.5-3 yr of age can identify the objects on a pediatric eye chart (Allen chart) at a distance of 15-20 ft.

The pupil reacts to light by 29-32 wk of corrected gestational age; however, the pupillary response is often difficult to evaluate, because premature infants resist eye opening and have poorly pigmented irises. Pupillary size, symmetry, and reactivity may be affected by drugs, space-occupying brain lesions, metabolic disorders, and abnormalities of the optic nerves and midbrain. A small pupil may be seen as part of the **Horner syndrome**—characterized by ipsilateral **ptosis** (droopy eyelid), **miosis** (constricted pupil), and **anhidrosis** (lack of sweating) of the face. Horner syndrome may be congenital or may be caused by a lesion of the sympathetic pathway in the hypothalamus, brainstem, cervical spinal cord, or sympathetic plexus. Localization of the lesion within the sympathetic nervous system may be obvious given the other signs present or may be uncertain. In the latter case, serial testing with cocaine drops followed by hydroxyamphetamine drops may be helpful.

During the examination of the pupil, any abnormalities of the iris should also be noted (e.g., heterochromia, Brushfield spots). The physician should also assess the posterior segment of the eye using the **red reflex** test, which is performed in a darkened room using a direct ophthalmoscope held close to the examiner's eye and 12-18 inches from the infant's eyes. If the posterior segment of the eye is normal, the examiner should see symmetric reddish-pink retinal reflections. The absence of any red reflex or the presence of a blunted reflex, white reflex (**leukocoria**), or red reflex with dark spots all signal pathology and should prompt referral to an ophthalmologist.

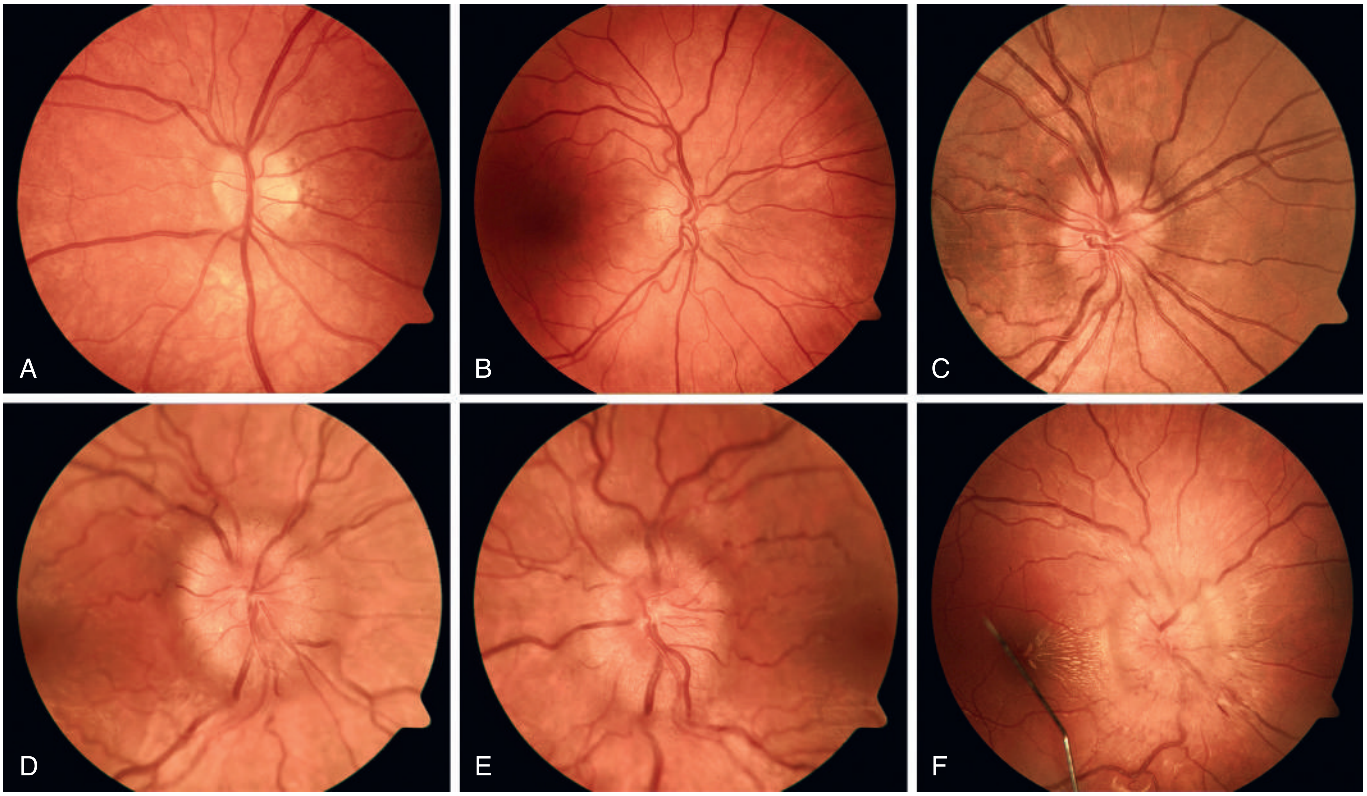

Figure 590-2 Stages of papilledema (Frisen scale). **A,** Stage 0: Normal optic disc. **B,** Stage 1: Very early papilledema with obscuration of the nasal border of the disc only, without elevation of the disc borders. **C,** Stage 2: Early papilledema showing obscuration of all borders, elevation of the nasal border, and a complete peripapillary halo. **D,** Stage 3: Moderate papilledema with elevation of all borders, increased diameter of the optic nerve head, obscuration of vessels at the disc margin, and a peripapillary halo with finger-like extensions. **E,** Stage 4: Marked papilledema characterized by elevation of the entire nerve head and total obscuration a segment of a major blood vessel on the disc. **F,** Stage 5: Severe papilledema with obscuration of all vessels and obliteration of the optic cup. Note also the nerve fiber layer hemorrhages and macular exudate. *(**A-C** courtesy Dr. Deborah Friedman; **D-F** courtesy Flaum Eye Institute, University of Rochester.)*

Oculomotor (Cranial Nerve III), Trochlear (Cranial Nerve IV), and Abducens Nerves (Cranial Nerve VI)

The globe is moved by 6 extraocular muscles, which are innervated by the oculomotor, trochlear, and abducens nerves. These muscles and nerves can be assessed by having the patient follow an interesting toy or the examiner's finger in the 6 cardinal directions of gaze. The physician observes the range and nature (conjugate vs dysconjugate, smooth vs choppy or saccadic) of the eye movements, particularly noting the presence and direction of any abnormal eye movements. Premature infants older than 25 wk of gestational age and comatose patients can be evaluated using the oculocephalic (doll's eye) maneuver, in which the patient's head is quickly rotated to evoke reflex eye movements. If the brainstem is intact, rotating the patient's head to the right causes the eyes to move to the left and vice versa. Similarly, rapid flexion and extension of the head elicits vertical eye movement.

Disconjugate gaze can result from extraocular muscle weakness; cranial nerve (CN) III, IV, or VI palsies; or brainstem lesions that disrupt the medial longitudinal fasciculus. Infants who are younger than 2 mo old can have slightly disconjugate gaze at rest, with 1 eye horizontally displaced from the other by 1 or 2 mm **(strabismus)**. Vertical displacement of the eyes requires investigation, as it can indicate trochlear nerve (CN IV) palsy or **skew deviation** (supranuclear ocular malalignment that is often associated with lesions of the posterior fossa). Strabismus is discussed further in Chapter 623.

The oculomotor nerve innervates the superior, inferior, and medial recti, as well as the inferior oblique and the levator palpebrae superioris muscles. Complete paralysis of the oculomotor nerve causes ptosis, dilation of the pupil, displacement of the eye outward and downward, and impairment of adduction and elevation. The trochlear nerve supplies the superior oblique muscle, which depresses and intorts the globe during activities such as reading and walking downstairs. Patients with an isolated paralysis of the trochlear nerve often have a compensatory head tilt away from the affected side, which helps to alleviate their diplopia. The abducens nerve innervates the lateral rectus muscle; its paralysis causes medial deviation of the eye with an inability to abduct beyond the midline. Patients with increased ICP often respond positively when questioned about double vision (**diplopia**) and exhibit incomplete abduction of the eyes on lateral gaze as a result of partial VIth nerve palsies. This false-localizing sign occurs because CN VI has a long intracranial course, making it particularly susceptible to being stretched. **Internuclear ophthalmoplegia,** caused by a lesion in the medial longitudinal fasciculus of the brainstem, that functionally serves conjugate gaze by connecting CN VI on one side to CN III on the other, results in paralysis of medial rectus function in the adducting eye and nystagmus in the abducting eye.

When there is a subtle eye movement abnormality, the **red glass test** may be helpful in localizing the lesion. To perform this test, a red glass is placed over one of the patient's eyes and the patient is instructed to follow a white light in all directions of gaze. The child sees 1 red/white light in the direction of normal muscle function but notes a separation of the red and white images that is greatest in the plane of action of the affected muscle.

In addition to gaze palsies, the examiner might encounter a variety of adventitious movements. **Nystagmus** is an involuntary, rapid movement of the eye that may be subclassified as being **pendular**, in which the 2 phases have equal amplitude and velocity, or **jerk**, in which there is a fast and slow phase. Jerk nystagmus can be further characterized by the direction of its fast phase, which may be left-, right-, up-, or downbeating; rotatory; or mixed. Many patients have a few beats of nystagmus with extreme lateral gaze **(end-gaze nystagmus),** which is

of no consequence. Pathologic horizontal nystagmus is most often congenital, drug-induced (e.g., alcohol, anticonvulsants), or a result of vestibular system dysfunction. By contrast, vertical nystagmus is often associated with structural abnormalities of the brainstem and cerebellum. **Ocular bobbing** is characterized by a downward jerk followed by a slow drift back to primary position and is associated with pontine lesions. **Opsoclonus** describes involuntary, chaotic oscillations of the eyes, which are often seen in the setting of neuroblastoma or viral infection.

Trigeminal Nerve (Cranial Nerve V)

The 3 divisions of the trigeminal nerve—ophthalmic, maxillary, and mandibular—convey information about facial protopathic (pain, temperature) and epicritic (vibration, proprioception) sensation. Each modality should be tested and compared to the contralateral side. In patients who are uncooperative or comatose, the integrity of the trigeminal nerve can be assessed by the corneal reflex, elicited by touching the cornea with a small pledget of cotton and observing for symmetric eye closure, and nasal tickle, obtained by stimulating the nasal passage with a cotton swab and observing for symmetric grimace. An absent reflex may be because of a sensory defect (trigeminal nerve) or a motor deficit (facial nerve). The motor division of the trigeminal nerve can be tested by examining the masseter, pterygoid, and temporalis muscles during mastication, as well as by evaluation of the jaw jerk.

Facial Nerve (Cranial Nerve VII)

The facial nerve is a predominantly motor nerve that innervates the muscles of facial expression, buccinator, platysma, stapedius, stylohyoid, and posterior belly of the digastric. It also has a separate division, called the chorda tympani, that contains sensory, special sensory (taste), and parasympathetic fibers. Because the portion of the facial nucleus that innervates the upper face receives bilateral cortical input, lesions of the motor cortex or corticobulbar tract have little effect on upper face strength. Rather, such lesions manifest with flattening of the contralateral nasolabial fold or drooping of the corner of the mouth. Conversely, lower motor neuron or facial nerve lesions tend to involve upper and lower facial muscles equally. Facial strength can be evaluated by observing the patient's spontaneous movements and by asking the patient to mimic a series of facial movements (e.g., smiling, raising the eyebrows, inflating the cheeks). A facial nerve palsy may be congenital; idiopathic (**Bell palsy**); or secondary to trauma, demyelination (Guillain-Barré syndrome), infection (Lyme disease, herpes simplex virus, HIV), granulomatous disease, neoplasm, or meningeal inflammation or infiltration. Facial nerve lesions that are proximal to the junction with the chorda tympani will result in an inability to taste substances with the anterior two-thirds of the tongue. If necessary, taste can be tested by placing a solution of saline or glucose on 1 side of the extended tongue. Normal children can identify the test substance in <10 sec. Other findings that may be associated with facial nerve palsy include hyperacusis, resulting from stapedius muscle involvement, and impaired tearing.

Vestibulocochlear Nerve (Cranial Nerve VIII)

The vestibulocochlear nerve has 2 components within a single trunk: the vestibular nerve, which innervates the semicircular canals of the inner ear and is involved with equilibrium, coordination, and orientation in space, and the cochlear nerve, which innervates the cochlea and subserves hearing.

Dysfunction of the vestibular system results in **vertigo**, the sensation of environmental motion. On examination, patients with vestibular nerve dysfunction typically have nystagmus, in which the fast component is directed away from the affected nerve. With their arms outstretched and eyes closed, their limbs tend to drift toward the injured side. Likewise, if they march in place, they slowly pivot toward the lesion (**Fukuda stepping test**). On Romberg and tandem gait testing, they tend to fall toward the abnormal ear. Vestibular function can be further evaluated with **caloric testing**. Before testing, the tympanic membrane should be visualized to ensure that it is intact and unobstructed. In an obtunded or comatose patient, 30-50 mL of ice water is then delivered by syringe into the external auditory canal with the patient's head elevated 30 degrees. If the brainstem is intact, the eyes deviate toward the irrigated side. A much smaller quantity of ice water (2 mL) is used in awake, alert patients to avoid inducing nausea. In normal subjects, introduction of ice water produces eye deviation toward the stimulated labyrinth followed by nystagmus with the fast component away from the stimulated labyrinth.

Because hearing is integral to normal language development, the physician should inquire directly about hearing problems. Parents' concern is often a reliable indicator of hearing impairment and warrants a formal audiologic assessment with either audiometry or brainstem auditory evoked potential testing (see Chapter 637). Even in the absence of parents' concern, certain children warrant formal testing within the 1st mo of life, including those with a family history of early life or syndromic deafness or a personal history of prematurity, severe asphyxia, exposure to ototoxic drugs, hyperbilirubinemia, congenital anomalies of the head or neck, bacterial meningitis, and congenital TORCH (*t*oxoplasmosis, *o*ther infections, *r*ubella, *c*ytomegalovirus, *h*erpes simplex virus) infections. For all other infants and children, a simple bedside assessment of hearing is usually sufficient. Newborns might have subtle responses to auditory stimuli, such as changes in breathing, cessation of movement, or opening of the eyes and/or mouth. If the same stimulus is presented repeatedly, normal neonates cease to respond, a phenomenon known as *habituation.* By 3-4 mo of age, infants begin to orient to the source of sound. Hearing-impaired toddlers are visually alert and appropriately responsive to physical stimuli but might have more frequent temper tantrums and abnormal speech and language development.

Glossopharyngeal Nerve (Cranial Nerve IX)

The glossopharyngeal nerve conveys motor fibers to the stylopharyngeus muscle; general sensory fibers from the posterior third of the tongue, pharynx, tonsil, internal surface of the tympanic membrane, and skin of the external ear; special sensory (taste) fibers from the posterior third of the tongue; parasympathetic fibers to the parotid gland; and general visceral sensory fibers from the carotid bodies. The nerve is tested by stimulating 1 side of the lateral oropharynx or soft palate with a tongue blade and observing for symmetric elevation of the palate **(gag reflex).** An isolated lesion of CN IX is rare, because it runs in close proximity to CN X. Potential causes of injury and/or dysfunction include birth trauma, ischemia, mass lesions, motor neuron disease, retropharyngeal abscess, and Guillain-Barré syndrome.

Vagus Nerve (Cranial Nerve X)

The vagus nerve has 10 terminal branches: meningeal, auricular, pharyngeal, carotid body, superior laryngeal, recurrent laryngeal, cardiac, pulmonary, esophageal, and gastrointestinal. The pharyngeal, superior laryngeal, and recurrent laryngeal branches contain motor fibers that innervate all of the muscles of the pharynx and larynx, with the exception of the stylopharyngeus (CN IX) and tensor veli palatini (CN V) muscles. Thus, unilateral injury of the vagus nerve results in weakness of the ipsilateral soft palate and a hoarse voice; bilateral lesions can produce respiratory distress as a result of vocal cord paralysis, as well as nasal regurgitation of fluids, pooling of secretions, and an immobile, low-lying soft palate. Isolated lesions to the vagus nerve may be a complication of thoracotomies or may be seen in neonates with type II Chiari malformations. If such a lesion is suspected, it is important to visualize the vocal cords. In addition to motor information, the vagus nerve carries somatic afferents from the pharynx, larynx, ear canal, external surface of the tympanic membrane, and meninges of the posterior fossa; visceral afferents; taste fibers from the posterior pharynx; and preganglionic parasympathetics.

Accessory Nerve (Cranial Nerve XI)

The accessory nerve innervates the sternocleidomastoid (SCM) and trapezius muscles. The left SCM acts to turn the head to the right side and vice versa; acting together, the SCMs flex the neck. The trapezius

acts to elevate the shoulder. Lesions to the accessory nerve result in atrophy and paralysis of the ipsilateral SCM and trapezius muscles, with resultant depression of the shoulder. Because several cervical muscles are involved in head rotation, unilateral SCM paresis might not be evident unless the patient is asked to rotate the head against resistance. Skull base fractures or lesions, motor neuron disease, myotonic dystrophy, and myasthenia gravis commonly produce atrophy and weakness of these muscles; congenital torticollis is associated with SCM hypertrophy.

Hypoglossal Nerve (Cranial Nerve XII)

The hypoglossal nerve innervates the tongue. Examination of the tongue includes assessment of its bulk and strength, as well as observation for adventitious movements. Malfunction of the hypoglossal nucleus or nerve produces atrophy, weakness, and fasciculations of the tongue. If the injury is unilateral, the tongue deviates toward the side of the injury; if it is bilateral, tongue protrusion is not possible and the patient can have difficulty swallowing (**dysphagia**). Werdnig-Hoffmann disease (infantile spinal muscular atrophy, or spinal muscular atrophy type 1) and congenital anomalies in the region of the foramen magnum are the principal causes of hypoglossal nerve dysfunction.

Motor Examination

The motor examination includes assessment of muscle bulk, tone, and strength, as well as observation for involuntary movements that might indicate central or peripheral nervous system pathology.

Bulk

Decreased muscle bulk **(atrophy)** may be secondary to disuse or to diseases of the lower motor neuron, nerve root, peripheral nerve, or muscle. In most cases, neurogenic atrophy is more severe than myogenic atrophy. Increased muscle bulk **(hypertrophy)** is usually physiologic (e.g., body builders). **Pseudohypertrophy** refers to muscle tissue that has been replaced by fat and connective tissue, giving it a bulky appearance with a paradoxical reduction in strength, as in Duchenne muscular dystrophy.

Tone

Muscle tone, which is generated by an unconscious, continuous, partial contraction of muscle, creates resistance to passive movement of a joint. Tone varies greatly based on a patient's age and state. At 28 wk of gestation, all 4 extremities are extended and there is little resistance to passive movement. Flexor tone is visible in the lower extremities at 32 wk and is palpable in the upper extremities at 36 wk; a normal-term infant's posture is characterized by flexion of all 4 extremities.

There are 3 key tests for assessing postural tone in neonates: the traction response, vertical suspension, and horizontal suspension (Fig. 590-3; see Chapters 94 and 97). To evaluate the **traction response**, the physician grasps the infant's hands and gently pulls the infant to a sitting position. Normally, the infant's head lags slightly behind the infant's body and then falls forward upon reaching the sitting position. To test **vertical suspension**, the physician holds the infant by the axillae without gripping the thorax. The infant should remain suspended with the infant's lower extremities held in flexion; a hypotonic infant will slip through the physician's hands. With **horizontal suspension**, the physician holds the infant prone by placing a hand under the infant's abdomen. The head should rise and the limbs should flex, but a hypotonic infant will drape over the physician's hand, forming a U shape. Assessing tone in the extremities is accomplished by observing the infant's resting position and passively manipulating the infant's limbs. When the upper extremity of a normal-term infant is pulled gently across the chest, the elbow does not quite reach the mid-sternum **(scarf sign),** whereas the elbow of a hypotonic infant extends beyond the midline with ease. Measurement of the **popliteal angle** is a useful method for documenting tone in the lower extremities. The examiner flexes the hip and extends the knee. Normal-term infants allow

Figure 590-3 Normal tone in a full-term neonate. **A,** Flexed resting posture. **B,** Traction response. **C,** Vertical suspension. **D,** Horizontal suspension.

extension of the knee to approximately 80 degrees. Similarly, tone can be evaluated by flexing the hip and knee to 90 degrees and then internally rotating the leg, in which case the heel should not pass the umbilicus.

Abnormalities of tone include spasticity, rigidity, and hypotonia. (Paratonia, which is rarely seen in the pediatric population, is not discussed here.) **Spasticity** is characterized by an initial resistance to passive movement, followed by a sudden release, referred to as the **clasp-knife** phenomenon. Because spasticity results from upper motor neuron dysfunction, it disproportionately affects the upper-extremity flexors and lower-extremity extensors and tends to occur in conjunction with disuse atrophy, hyperactive deep tendon reflexes, and extensor plantar reflexes **(Babinski sign).** In infants, spasticity of the lower extremities results in scissoring of the legs upon vertical suspension. Older children can present with prolonged commando crawling or toe-walking. **Rigidity,** seen with lesions of the basal ganglia, is characterized by resistance to passive movement that is equal in the flexors and extensors regardless of the velocity of movement **(lead pipe).** Patients with either spasticity or rigidity might exhibit **opisthotonos**, defined as severe hyperextension of the spine caused by hypertonia of the paraspinal muscles (Fig. 590-4), although similar posturing can be seen in patients with Sandifer syndrome (gastroesophageal reflux or hiatal hernia associated with torsional dystonia). **Hypotonia** refers to abnormally diminished tone and is the most common abnormality of tone in neurologically compromised neonates. A hypotonic infant is floppy and often assumes a frog-leg posture at rest. Hypotonia can reflect pathology of the cerebral hemispheres, cerebellum, spinal cord, anterior horn cell, peripheral nerve, neuromuscular junction, or muscle.

Figure 590-4 Opisthotonus in a brain-injured infant.

Strength

Older children are usually able to cooperate with formal strength testing, in which case muscle power is graded on a scale of 0-5 as follows: 0 = no contraction; 1 = flicker or trace of contraction; 2 = active movement with gravity eliminated; 3 = active movement against gravity; 4 = active movement against gravity and resistance; 5 = normal power. An examination of muscle power should include all muscle groups, including the neck flexors and extensors and the muscles of respiration. It is important not only to assess individual muscle groups, but also to determine the pattern of weakness (i.e., proximal vs distal; segmental vs regional). Testing for **pronator drift** can be helpful in localizing the lesion in a patient with weakness. This test is accomplished by having the patient extend his or her arms away from the body with the palms facing upward and the eyes closed. *Together, pronation and downward drift of an arm indicate a lesion of the contralateral corticospinal tract.*

Because infants and young children are not able to participate in formal strength testing, they are best assessed with functional measures. Proximal and distal strength of the upper extremities can be tested by having the child reach overhead for a toy and by watching the child manipulate small objects. In infants younger than 2 mo old, the physician can also take advantage of the palmar grasp reflex in assessing distal power and the Moro reflex in assessing proximal power. Infants with decreased strength in the lower extremities tend to have diminished spontaneous activity in their legs and are unable to support their body weight when held upright. Older children may have difficulty climbing or descending steps, jumping, or hopping. They might also use their hands to "climb up" their legs when asked to rise from a prone position, a maneuver called **Gowers sign** (Fig. 590-5).

Involuntary Movements

Patients with lower motor neuron or peripheral nervous system lesions might have **fasciculations**, which are small, involuntary muscle contractions that result from the spontaneous discharge of a single motor unit and create the illusion of a "bag of worms" under the skin. Because most infants have abundant body fat, muscle fasciculations are best observed in the tongue in this age group.

Most other involuntary movements, including tics, dystonia, chorea, and athetosis, stem from disorders of the basal ganglia. Tremor seems

Figure 590-5 A-D, Gowers sign in a boy with hip girdle weakness because of Duchenne muscular dystrophy. When asked to rise from a prone position, the patient uses his hands to walk up his legs to compensate for proximal lower-extremity weakness.

Table 590-2 Timing of Selected Primitive Reflexes

REFLEX	ONSET	FULLY DEVELOPED	DURATION
Palmar grasp	28 wk gestation	32 wk gestation	2-3 mo postnatal
Rooting	32 wk gestation	36 wk gestation	Less prominent after 1 mo postnatal
Moro	28-32 wk gestation	37 wk gestation	5-6 mo postnatal
Tonic neck	35 wk gestation	1 mo postnatal	6-7 mo postnatal
Parachute	7-8 mo postnatal	10-11 mo postnatal	Remains throughout life

to be an exception, as it is thought to be mediated by cerebellothalamocortical pathways. Further detail on the individual movement disorders is provided in Chapter 597.

Sensory Examination

The sensory examination is difficult to perform on an infant or uncooperative child and has a relatively low yield in terms of the information that it provides. A gross assessment of sensory function can be achieved by distracting the patient with an interesting toy and then touching the patient with a cotton swab in different locations. Normal infants and children indicate an awareness of the stimulus by crying, withdrawing the extremity, or pausing briefly; however, with repeated testing, they lose interest in the stimulus and begin to ignore the examiner. It is critical, therefore, that any areas of concern are tested efficiently and, if necessary, reexamined at an appropriate time.

Fortunately, isolated disorders of the sensory system are less common in the very young pediatric population than in the adult population, so detailed sensory testing is rarely warranted. Furthermore, most patients who are old enough to voice a sensory complaint are also old enough to cooperate with formal testing of light touch, pain, temperature, vibration, proprioception, and corticosensation (e.g., stereognosis, 2-point discrimination, extinction to double simultaneous stimulation). A notable exception is when the physician suspects a spinal cord lesion in an infant or young child and needs to identify a sensory level. In such situations, observation might suggest a difference in color, temperature, or perspiration, with the skin cool and dry below the level of injury. Lightly touching the skin above the level can evoke a squirming movement or physical withdrawal. Other signs of spinal cord injury include decreased anal sphincter tone and strength and absence of the superficial abdominal, anal wink, and cremasteric reflexes.

Reflexes

Deep Tendon Reflexes and the Plantar Response

Deep tendon reflexes are readily elicited in most infants and children. In infants, it is important to position the head in the midline when assessing reflexes, because turning the head to 1 side can alter reflex tone. Reflexes are graded from 0 (absent) to 4+ (markedly hyperactive), with 2+ being normal. Reflexes that are 1+ or 3+ can be normal as long as they are symmetrical. Sustained clonus is always pathologic, but infants younger than 3 mo old can have 5-10 beats of clonus, and older children can have 1-2 beats of clonus, provided that it is symmetrical.

The ankle jerk is hardest to elicit, but it can usually be obtained by passively dorsiflexing the foot and then tapping on either the Achilles tendon or the ball of the foot. The knee jerk is evoked by tapping the patellar tendon. If this reflex is exaggerated, extension of the knee may be accompanied by contraction of the contralateral adductors **(crossed adductor response).** Hypoactive reflexes reflect lower motor neuron or cerebellar dysfunction, whereas hyperactive reflexes are consistent with upper motor neuron disease. The plantar response is obtained by stimulation of the lateral aspect of the sole of the foot, beginning at the heel and extending to the base of the toes. The **Babinski sign,** indicating an upper motor neuron lesion, is characterized by extension of the great toe and fanning of the remaining toes. Too vigorous stimulation may produce withdrawal, which may be misinterpreted as a Babinski sign. Plantar responses have limited diagnostic utility in neonates, because they are mediated by several competing reflexes and can be either flexor or extensor, depending on how the foot is positioned. Asymmetry of the reflexes or plantar response is a useful lateralizing sign in infants and children.

Primitive Reflexes

Primitive reflexes appear and disappear at specific times during development (Table 590-2), and their absence or persistence beyond those times signifies CNS dysfunction. Although many primitive reflexes have been described, the Moro, grasp, tonic neck, and parachute reflexes are the most clinically relevant. The **Moro reflex** is elicited by supporting the infant in a semierect position and then allowing the infant's head to fall backwards onto the examiner's hand. A normal response consists of symmetric extension and abduction of the fingers and upper extremities, followed by flexion of the upper extremities and an audible cry. An asymmetric response can signify a fractured clavicle, brachial plexus injury, or hemiparesis. Absence of the Moro reflex in a term newborn is ominous, suggesting significant dysfunction of the CNS. The **grasp response** is elicited by placing a finger in the open palm of each hand; by 37 wk of gestation, the reflex is strong enough that the examiner can lift the infant from the bed with gentle traction. The **tonic neck reflex** is produced by manually rotating the infant's head to 1 side and observing for the characteristic fencing posture (extension of the arm on the side to which the face is rotated and flexion of the contralateral arm). An obligatory tonic neck response, in which the infant becomes "stuck" in the fencing posture, is always abnormal and implies a CNS disorder. The **parachute reflex**, which occurs in slightly older infants, can be evoked by holding the infant's trunk and then suddenly lowering the infant as if he or she were falling. The arms will spontaneously extend to break the infant's fall, making this reflex a prerequisite to walking.

Coordination

Ataxia refers to a disturbance in the smooth performance of voluntary motor acts and is usually the result of cerebellar dysfunction. Lesions to the cerebellar vermis result in unsteadiness while sitting or standing **(truncal ataxia).** Affected patients might have a wide-based gait or may be unable to perform tandem gait testing. Lesions of the cerebellar hemispheres cause appendicular ataxia, which may be apparent as the patient reaches for objects and performs finger-to-nose and heel-to-shin movements. Other features of cerebellar dysfunction include errors in judging distance **(dysmetria),** inability to inhibit a muscular action **(rebound),** impaired performance of rapid alternating movements **(dysdiadochokinesia),** intention tremor, nystagmus, scanning dysarthria, hypotonia, and decreased deep tendon reflexes. Acute ataxia suggests an infectious or postinfectious, endocrinologic, toxic, traumatic, vascular, or psychogenic process, and chronic symptoms suggest a metabolic, neoplastic, or degenerative process.

Station and Gait

Observation of a child's station and gait is an important aspect of the neurologic examination. Normal children can stand with their feet close together without swaying; however, children who are unsteady may sway or even fall. On gait testing, the heels should strike either side of an imaginary line, but children with poor balance tend to walk with their legs farther apart to create a more stable base. Tandem gait

testing forces patients to have a narrow base, which highlights subtle balance difficulties.

There are a variety of abnormal gaits, many of which are associated with a specific underlying etiology. Patients with a **spastic** gait appear stiff-legged like a soldier. They may walk on tiptoe as a result of tightness or contractures of the Achilles tendons, and their legs may scissor as they walk. A **hemiparetic** gait is associated with spasticity and circumduction of the leg, as well as decreased arm swing on the affected side. **Cerebellar ataxia** results in a wide-based, reeling gait like a drunk person, whereas **sensory ataxia** results in a wide-based **steppage gait,** in which the patient lifts the legs up higher than usual in the swing phase and then slaps the foot down. A **myopathic,** or waddling, gait is associated with hip girdle weakness. Affected children often develop a compensatory lordosis and have other signs of proximal muscle weakness, such as difficulty climbing stairs. During gait testing, the examiner might also note hypotonia or weakness of the lower extremities; extrapyramidal movements, such as dystonia or chorea; or orthopedic deformities, such as pelvic tilt, genu recurvatum, varus or valgus deformities of the knee, pes cavus (high arches) or pes planus (flat feet), and scoliosis.

GENERAL EXAMINATION

Examination of other organ systems is essential because myriad systemic diseases affect the nervous system. Dysmorphic features can indicate a genetic syndrome (see Chapter 108). Heart murmurs may be associated with rheumatic fever (Sydenham chorea), cardiac rhabdomyoma (tuberous sclerosis), cyanotic heart disease (cerebral abscess or thrombosis), and endocarditis (cerebral vascular occlusion). Hepatosplenomegaly can suggest an inborn error of metabolism, storage disease, HIV, or malignancy. Cutaneous lesions may be a feature of a neurocutaneous syndrome (see Chapter 596).

SPECIAL DIAGNOSTIC PROCEDURES

Lumbar Puncture and Cerebrospinal Fluid Examination

Examination of the cerebrospinal fluid (CSF) and measurement of the pressure it creates in the subarachnoid space are essential in confirming the diagnosis of meningitis, encephalitis, and idiopathic intracranial hypertension (previously referred to as pseudotumor cerebri), and it is often helpful in assessing subarachnoid hemorrhage; demyelinating, degenerative, and collagen vascular diseases; and intracranial neoplasms. Having an experienced assistant who can position, restrain, and comfort the patient is critical to the success of the procedure.

The patient should be situated in a lateral decubitus or seated position with the neck and legs flexed to enlarge the intervertebral spaces. As a rule, sick neonates should be maintained in a seated position to prevent problems with ventilation and perfusion. Regardless of the position chosen, it is important to make sure that the patient's shoulders and hips are straight to prevent rotating the spine.

Once the patient is situated, the physician identifies the appropriate interspace by drawing an imaginary line from the iliac crest downward perpendicular to the vertebral column. In adults, lumbar punctures are usually performed in the L3-L4 or L4-L5 interspaces. Next, the physician dons a mask, gown, and sterile gloves. The skin is thoroughly prepared with a cleansing agent, and sterile drapes are applied. The skin and underlying tissues are anesthetized by injecting a local anesthetic (e.g., 1% lidocaine) at the time of the procedure or by applying a eutectic mixture of lidocaine and prilocaine (EMLA) to the skin 30 minutes before the procedure. A 22-gauge, 1.5-3.0 in, sharp, beveled spinal needle with a properly fitting stylet is introduced in the midsagittal plane and directed slightly cephalad. The physician should pause frequently, remove the stylet, and assess for CSF flow. Although a pop can occur as the needle penetrates the dura, it is more common to experience a subtle change in resistance.

Once CSF has been detected, a manometer and 3-way stopcock can be attached to the spinal needle to obtain an opening pressure. If the patient was seated as the spinal needle was introduced, the patient should be moved carefully to a **lateral decubitus position** with the head and legs extended before the manometer is attached. Normal opening pressures are 90-120 mm H_2O in newborns, 60-180 mm H_2O in young children, and 12-120 mm H_2O in older children and adults. The 90th percentile in children has been reported to be 250 mm of H_2O. The most common cause of an elevated opening pressure is an agitated patient. Sedation and high body mass index can also increase the opening pressure.

Contraindications to performing a lumbar puncture include suspected mass lesion of the brain, especially in the posterior fossa or above the tentorium and causing shift of the midline; suspected mass lesion of the spinal cord; symptoms and signs of impending cerebral herniation in a child with probable meningitis; critical illness (on rare occasions); skin infection at the site of the lumbar puncture; and thrombocytopenia with a platelet count $<20 \times 10^9$/L. If disc edema or focal findings suggest a mass lesion, a head CT should be obtained before proceeding with lumbar puncture to prevent uncal or cerebellar herniation as the CSF is removed. In the absence of these findings, routine head imaging is not warranted. The physician should also be alert to clinical signs of impending herniation, including alterations in the respiratory pattern (e.g., hyperventilation; Cheyne-Stokes respirations, ataxic respirations, respiratory arrest), abnormalities of pupil size and reactivity, loss of brainstem reflexes, and decorticate or decerebrate posturing. If any of these signs are present or the child is so ill that the lumbar puncture might induce cardiorespiratory arrest, blood cultures should be drawn and supportive care, including antibiotics, should be initiated. Once the patient has stabilized, it may be possible to perform a lumbar puncture safely.

Normal CSF contains up to 5/mm^3 white blood cells, and a newborn can have as many as 15/mm^3. Polymorphonuclear cells are always abnormal in a child, but 1-2/mm^3 may be present in a normal neonate. An elevated polymorphonuclear count suggests bacterial meningitis or the early phase of aseptic meningitis (see Chapter 603). CSF lymphocytosis can be seen in aseptic, tuberculous, or fungal meningitis; demyelinating diseases; brain or spinal cord tumor; immunologic disorders, including collagen vascular diseases; and chemical irritation (following myelogram, intrathecal methotrexate).

Normal CSF contains no red blood cells; thus, their presence indicates a traumatic tap or a subarachnoid hemorrhage. Progressive clearing of the blood between the first and last samples indicates a traumatic tap. Bloody CSF should be centrifuged immediately. A clear supernatant is consistent with a bloody tap, whereas **xanthochromia** (yellow color that results from the degradation of hemoglobin) suggests a subarachnoid hemorrhage. Xanthochromia may be absent in bleeds <12 hr old, particularly when laboratories rely on visual inspection rather than spectroscopy. Xanthochromia can also occur in the setting of hyperbilirubinemia, carotenemia, and markedly elevated CSF protein.

The normal CSF protein is 10-40 mg/dL in a child and as high as 120 mg/dL in a neonate. The CSF protein falls to the normal childhood range by 3 mo of age. The CSF protein may be elevated in many processes, including infectious, immunologic, vascular, and degenerative diseases, blockage of CSF flow, as well as tumors of the brain (primary CNS tumors, systemic tumors metastatic to the CNS, infiltrative acute lymphoblastic leukemia) and spinal cord. With a traumatic tap, the CSF protein is increased by approximately 1 mg/dL for every 1,000 red blood cells/mm^3. Elevation of CSF immunoglobulin G, which normally represents approximately 10% of the total protein, is observed in subacute sclerosing panencephalitis, in postinfectious encephalomyelitis, and in some cases of multiple sclerosis. If the diagnosis of multiple sclerosis is suspected, the CSF should be tested for the presence of oligoclonal bands.

The CSF glucose content is approximately 60% of the blood glucose in a healthy child. To prevent a spuriously elevated blood:CSF glucose ratio in a case of suspected meningitis, it is advisable to collect the blood glucose before the lumbar puncture when the child is relatively calm. Hypoglycorrhachia is found in association with diffuse meningeal disease, particularly bacterial and tubercular meningitis. Widespread neoplastic involvement of the meninges, subarachnoid hemorrhage, disorders involving the glucose transporter protein type 1, fungal meningitis, and, occasionally, aseptic meningitis can produce low CSF glucose as well.

A Gram stain of the CSF is essential if there is a suspicion for bacterial meningitis; an acid-fast stain and India ink preparation can be used to assess for tuberculous and fungal meningitis, respectively. CSF is then plated on different culture media depending on the suspected pathogen. When indicated by the clinical presentation, it can also be helpful to assess for the presence of specific antigens (e.g., latex agglutination for *Neisseria meningitidis*, *Haemophilus influenzae* type b, or *Streptococcus pneumoniae*) or to obtain antibody or polymerase chain reaction studies (e.g., herpes simplex virus-1 and -2, West Nile virus, enteroviruses). In noninfectious cases, levels of CSF metabolites, such as lactate, amino acids, and enolase, can provide clues to the underlying metabolic disease.

Neuroradiologic Procedures

Skull roentgenograms have limited diagnostic utility. They can demonstrate fractures, bony defects, intracranial calcifications, or indirect evidence of increased ICP. Acutely increased ICP causes separation of the sutures, whereas chronically increased ICP is associated with erosion of the posterior clinoid processes, enlargement of the sella turcica, and increased convolutional markings.

Cranial ultrasonography is the imaging method of choice for detecting intracranial hemorrhage, periventricular leukomalacia, and hydrocephalus in infants with patent anterior fontanels. Ultrasound is less sensitive than either CT or MRI for detecting hypoxic–ischemic injury, but the use of color Doppler or power Doppler sonography, both of which show changes in regional cerebral blood flow, improve its sensitivity. In general, ultrasound is not a useful technique in older children, although it can be helpful intraoperatively when placing shunts, locating small tumors, and performing needle biopsies.

CT is a valuable diagnostic tool in the evaluation of many neurologic emergencies, as well as some nonemergent conditions. It is a noninvasive, rapid procedure that can usually be performed without sedation. CT scans use conventional x-ray techniques, meaning that they produce ionizing radiation. Because children younger than 10 yr of age are several times more sensitive to radiation than adults, it is important to consider the whether imaging is actually indicated and, if it is, whether an ultrasound or MRI might be the more appropriate study. In the emergency setting, a noncontrast CT scan can demonstrate skull fractures, pneumocephalus, intracranial hemorrhages, hydrocephalus, and impending herniation. If the noncontrast scan reveals an abnormality and an MRI cannot be performed in a timely fashion, nonionic contrast should be used to highlight areas of breakdown in the blood–brain barrier (e.g., abscesses, tumors) and/or collections of abnormal blood vessels (e.g., arteriovenous malformations). CT is less useful for diagnosing acute infarcts in children, because radiographic changes might not be apparent for up to 24 hr. Some subtle signs of early (<24 hr) infarction include sulcal effacement, blurring of the gray–white junction, and the hyperdense middle cerebral artery sign (increased attenuation in the middle cerebral artery that is often associated with thrombosis). In the routine setting, CT imaging can be used to demonstrate intracranial calcifications or, with the addition of 3-dimensional reformatting, to evaluate patients with craniofacial abnormalities or craniosynostosis. Although other pathologic processes may be visible on CT scan, *MR is generally preferred because it provides a more-detailed view of the anatomy without exposure to ionizing radiation* (Table 590-3).

CT angiography is a useful tool for visualizing vascular structures and is accomplished by administering a tight bolus of iodinated contrast through a large-bore intravenous catheter and then acquiring CT images as the contrast passes through the arteries.

MRI is a noninvasive procedure that is well suited for detecting a variety of abnormalities, including those of the posterior fossa and spinal cord. MR scans are highly susceptible to patient motion artifact; consequently, many children younger than age 8 yr require sedation to ensure an adequate study. (The need for sedation is beginning to change in some centers as MRI technology improves and allows for faster performance of studies.) Because the American Academy of Pediatrics recommends that infants be kept nothing by mouth (NPO) for 4 hr or longer and older children for 6 hr or longer before deep sedation, it is often difficult to obtain an MRI on an infant or young child in the acute setting. MRI can be used to evaluate for congenital or acquired brain lesions, migrational defects, dysmyelination or demyelination, posttraumatic gliosis, neoplasms, cerebral edema, and acute stroke (see Table 590-3). Paramagnetic MR contrast agents (e.g., gadolinium-diethylenetriaminepentaacetic acid [DTPA]) are efficacious in identifying areas of disruption in the blood–brain barrier, such as those occurring in primary and metastatic brain tumors, meningitis, cerebritis, abscesses, and active demyelination. **MR angiography** and **MR venography** provide detailed images of major intracranial vasculature structures and assist in the diagnosis of conditions such as stroke, vascular malformations, and cerebral venous sinus thrombosis. MR angiography is the procedure of choice for infants and young children owing to the lack of ionizing radiation and contrast; however, CT angiography may be preferable in older children because it is faster and can eliminate the need for sedation; it is particularly useful for looking at blood vessels in the neck, where there is less interference from bone artifact than in the skull-encased brain.

Functional MRI is a noninvasive technique used to map neuronal activity during specific cognitive states and/or sensorimotor functions. Data are usually based on blood oxygenation, although they can also be based on local cerebral blood volume or flow. Functional MRI is useful for presurgical localization of critical brain functions and has several advantages over other functional imaging techniques. Specifically, functional MRI produces high-resolution images without exposure to ionizing radiation or contrast, and it allows coregistration of functional and structural images.

Proton MR spectroscopy (MRS) is a molecular imaging technique in which the unique neurochemical profile of a preselected brain region is displayed in the form of a spectrum. Many metabolites can be detected, the most common of which are *N*-acetylaspartate, creatine and phosphocreatine, choline, myoinositol, and lactate. Changes in the spectral pattern of a given area can yield clues to the underlying pathology, making MRS useful in the diagnosis of inborn errors of metabolism, as well as the preoperative and posttherapeutic assessment of intracranial tumors. MRS can also detect areas of cortical dysplasia in patients with epilepsy, because these patients have low *N*-acetylaspartate:creatine ratios. Finally, MRS may be useful in detecting hypoxic–ischemic injury in newborns in the 1st day of life, because the lactate peak enlarges and the *N*-acetylaspartate peak diminishes before MRI sequences become abnormal.

Catheter angiography is the gold standard for diagnosing vascular disorders of the CNS, such as arteriovenous malformations, aneurysms, arterial occlusions, and vasculitis. A 4-vessel study is accomplished by introducing a catheter into the femoral artery and then injecting contrast media into each of the internal carotid and vertebral arteries. Because catheter angiography is invasive and requires general anesthesia, it is typically reserved for treatment planning of endovascular or open procedures and for cases in which noninvasive imaging results are not diagnostic.

Positron emission tomography provides unique information on brain metabolism and perfusion by measuring blood flow, oxygen uptake, and/or glucose consumption. Positron emission tomography is an expensive technique that is gaining a following in some pediatric centers, particularly those with active epilepsy surgery programs. **Single-photon emission CT** using ^{99m}Tc hexamethylpropyleneamine oxime is a sensitive and inexpensive technique to study regional cerebral blood flow. Single-photon emission CT is particularly useful in assessing for vasculitis, herpes encephalitis, dysplastic cortex, and recurrent brain tumors. Positron emission tomography MRI is only available in a few pediatric centers in the United States; it provides better resolution and tissue definition than single-photon emission CT.

Electroencephalography

An electroencephalogram (EEG) provides a continuous recording of electrical activity between reference electrodes placed on the scalp. Although the genesis of the electrical activity is not certain, it likely originates from postsynaptic potentials in the dendrites of cortical neurons. Even with amplification of the electrical activity, not all potentials are recorded because there is a buffering effect of the scalp, muscles, bone, vessels, and subarachnoid fluid. EEG waves are

Table 590-3 Preferred Imaging Procedures in Neurologic Diseases

ISCHEMIC INFARCTION OR TRANSIENT ISCHEMIC ATTACK CT/CTA (head and neck) ± CT perfusion for patients who are unstable or are potential candidates for tissue plasminogen activator or other acute interventions Otherwise, MRI/MRA (head and neck) with and without gadolinium and with diffusion-weighted images If the examination findings localize to the anterior circulation, carotid ultrasound should be performed rather than neck CTA or MRA Obtain an MRV if the infarct does not follow an arterial distribution CT or MRI can detect infarcts more than 24 hr old, although MRI is generally preferred to avoid exposure to ionizing radiation	HEADACHE CT with and without contrast or MRI with and without gadolinium if a structural disorder is suspected (MRI is preferred in nonemergent situations as it does not involve ionizing radiation and provides a better view of the parenchyma)
INTRAPARENCHYMAL HEMORRHAGE CT if <24 hr; MRI if >24 hr MRI and MRA to assess for underlying vascular malformation, tumor, etc. Catheter angiography if MRA is nondiagnostic	HEAD TRAUMA CT without contrast initially MRI after initial assessment and treatment if clinically indicated. Diffusion tensor imaging and/or diffusion kurtosis sequences may be useful to detect subtle white matter abnormalities
ARTERIOVENOUS MALFORMATION CT for acute hemorrhage; MRI and MRA with and without gadolinium as early as possible Catheter angiography if noninvasive imaging is nondiagnostic	EPILEPSY MRI with and without gadolinium. Thin slices through the mesial temporal lobes may be helpful if a temporal focus is suspected PET Interictal SPECT
CEREBRAL ANEURYSM CT without contrast for acute subarachnoid hemorrhage MRA or CTA to identify the aneurysm Catheter angiography may be necessary in some cases TCD to detect vasospasm	BRAIN TUMOR MRI with and without gadolinium MRS PET
HYPOXIC–ISCHEMIC BRAIN INJURY Ultrasound in infants If ultrasound is negative or there is a discrepancy between the clinical course and the sonogram, obtain an MRI In older children, CT if unstable; otherwise, MRI MRS can show a lactate peak even in the absence of structural abnormalities and can be useful for prognostication purposes	MULTIPLE SCLEROSIS MRI with and without gadolinium Obtain sagittal FLAIR images
METABOLIC DISORDERS MRI, particularly T2-weighted and FLAIR images Diffusion-weighted images may be useful in distinguishing acute and chronic changes MRS, SPECT, and PET may be useful in certain disorders	MENINGITIS OR ENCEPHALITIS CT without and with contrast before lumbar puncture if there are signs of increased ICP on examination MRI with and without gadolinium after initial assessment and treatment for patients with complicated meningitis or encephalitis
HYDROCEPHALUS Ultrasound (in infants), CT with and without contrast, or MR with and without gadolinium for diagnosis of communicating hydrocephalus MR with and without gadolinium for diagnosis of noncommunicating hydrocephalus Ultrasound (in infants) or CT to follow ventricular size in response to treatment	BRAIN ABSCESS MRI with and without gadolinium Diffusion-weighted images and MRS can help to differentiate abscess from necrotic tumor If the patient is unstable, CT with and without contrast followed by MRI with and without contrast when feasible MOVEMENT DISORDERS MRI with and without gadolinium PET DaTscan (SPECT scan using ioflupane iodine-123 as the contrast agent for detecting dopamine transporters in suspected parkinsonian syndromes)

CTA, computed tomographic angiography; FLAIR, fluid-attenuated inversion recovery; ICP, intracranial pressure; MRA, magnetic resonance angiography; MRS, magnetic resonance spectroscopy; MRV, magnetic resonance venography; PET, positron emission tomography; SPECT, single-photon emission computed tomography; TCD, transcranial Doppler ultrasonography.

classified according to their frequency as delta (1-3/sec), theta (4-7/sec), alpha (8-12/sec), and beta (13-20/sec). These waves are altered by many factors, including age, level of alertness, eye closure, drugs, and disease states.

The normal waking EEG is characterized by the posterior dominant rhythm—a sinusoidal, 8-12 Hz rhythm that is most prominent over the occipital region in a state of relaxed wakefulness with the eyes closed. This rhythm first becomes apparent at 3-4 mo old, and most children have achieved the adult frequency of 8-12 Hz by age 8 yr.

Normal sleep is divided into 3 stages of non–rapid eye movement sleep—designated N1, N2, and N3—and rapid eye movement sleep. N1 corresponds to drowsiness, and N3 represents deep, restorative, slow-wave sleep. Rapid eye movement sleep is rarely captured during a routine EEG but may be seen on an overnight recording. The American Electroencephalography Society Guideline and Technical Standards states that "sleep recordings should be obtained whenever possible"; however, it appears that sleep deprivation—not sleep during the EEG—is what increases the yield of the study, particularly in children with 1 or more clinically diagnosed seizures and in children older than 3 yr of age.

EEG abnormalities can be divided into 2 general categories: epileptiform discharges and slowing. Epileptiform discharges are paroxysmal spikes or sharp waves, often followed by slow waves, which interrupt the background activity. They may be focal, multifocal, or generalized. Focal discharges are often associated with cerebral dysgenesis or irritative lesions, such as cysts, slow-growing tumors, or glial scar tissue; generalized discharges typically occur in children with structurally normal brains. Generalized discharges can occur as an epilepsy trait in children who have never had a seizure and, by themselves, are not an indication for treatment. Epileptiform activity may be enhanced by activation procedures, including hyperventilation and photic stimulation.

As with epileptiform discharges, slowing can be either focal or diffuse. Focal slowing should raise a concern for an underlying functional or structural abnormality, such as an infarct, hematoma, or tumor. Diffuse slowing is the hallmark of encephalopathy and is usually secondary to a widespread disease process or toxic–metabolic insult.

Long-term video EEG monitoring provides precise characterization of seizure types, which allows specific medical or surgical management. It facilitates more accurate differentiation of epileptic seizures

from paroxysmal events that mimic epilepsy, including psychogenic nonepileptiform attacks. Long-term EEG monitoring can also be useful during medication adjustments.

Evoked Potentials

An evoked potential is an electrical signal recorded from the CNS following the presentation of a specific visual, auditory, or sensory stimulus. Stimulation of the visual system by a flash or patterned stimulus, such as a black-and-white checkerboard, produces **visual evoked potentials** (VEPs), which are recorded over the occiput and averaged in a computer. Abnormal VEPs can result from lesions to the visual pathway anywhere from the retina to the visual cortex. Many demyelinating disorders and neurodegenerative diseases, such as Tay-Sachs, Krabbe, or Pelizaeus-Merzbacher disease, or neuronal ceroid lipofuscinoses, show characteristic VEP abnormalities. Flash VEPs can also be helpful in evaluating infants who have sustained an anoxic injury; however, detection of an evoked potential does not necessarily mean that the infant will have functional vision.

Brainstem auditory evoked responses (BAERs) provide an objective measure of hearing and are particularly useful in neonates and in children who have failed, or are uncooperative with, audiometric testing. BAERs are abnormal in many neurodegenerative diseases of childhood and are an important tool in evaluating patients with suspected tumors of the cerebellopontine angle. BAERs can be helpful in assessing brainstem function in comatose patients, because the waveforms are unaffected by drugs or by the level of consciousness; however, they are not accurate in predicting neurologic recovery and outcome.

Somatosensory evoked potentials (SSEPs) are obtained by stimulating a peripheral nerve (peroneal, median) and then recording the electrical response over the cervical region and contralateral parietal somatosensory cortex. SSEPs determine the functional integrity of the dorsal column–medial lemniscal system and are useful in monitoring spinal cord function during operative procedures for scoliosis, aortic coarctation, and myelomeningocele repair. SSEPs are abnormal in many neurodegenerative disorders and are the most accurate evoked potential in the assessment of neurologic outcome following a severe CNS insult.

Chapter 591
Congenital Anomalies of the Central Nervous System

Stephen L. Kinsman and Michael V. Johnston

Central nervous system (CNS) malformations are grouped into neural tube defects and associated spinal cord malformations; encephaloceles; disorders of structure specification (gray matter structures, neuronal migration disorders, disorders of connectivity, and commissure and tract formation); disorders of the posterior fossa, brainstem, and cerebellum; disorders of brain growth and size; and disorders of skull growth and shape. Classification of these conditions into syndromic, nonsyndromic, and single-gene etiologies is also important. These disorders can also be seen as isolated findings or as being a consequence of environmental exposures. Elucidation of single-gene causes has outpaced our understanding of the epigenetic and environmental mechanisms causing these malformations.

These disorders are heterogeneous in their presentation. Common presentations and clinical problems include disorders of head size and/or shape; hydrocephalus; fetal ultrasonographic brain abnormalities; neonatal encephalopathy and seizures; developmental delay, cognitive impairment, and intellectual disability; hypotonia, motor impairment, and cerebral palsy; seizures, epilepsy, and drug-resistant epilepsy; cranial nerve dysfunction; and spinal cord dysfunction.

Bibliography is available at Expert Consult.

591.1 Neural Tube Defects

Stephen L. Kinsman and Michael V. Johnston

Neural tube defects (NTDs) account for the largest proportion of congenital anomalies of the CNS and result from failure of the neural tube to close spontaneously between the 3rd and 4th wk of in utero development. Although the precise cause of NTDs remains unknown, evidence suggests that many factors, including hyperthermia, drugs (valproic acid), malnutrition, low red cell folate levels, chemicals, maternal obesity or diabetes, and genetic determinants (mutations in folate-responsive or folate-dependent enzyme pathways) can adversely affect normal development of the CNS from the time of conception. In some cases, an abnormal maternal nutritional state or exposure to radiation before conception increases the likelihood of a congenital CNS malformation. The major NTDs include spina bifida occulta, meningocele, myelomeningocele, encephalocele, anencephaly, caudal regression syndrome, dermal sinus, tethered cord, syringomyelia, diastematomyelia, and lipoma involving the conus medullaris and/or filum terminale and the rare condition iniencephaly.

The human nervous system originates from the primitive ectoderm that also develops into the epidermis. The ectoderm, endoderm, and mesoderm form the three primary germ layers that are developed by the 3rd wk. The endoderm, particularly the notochordal plate and the intraembryonic mesoderm, induces the overlying ectoderm to develop the neural plate in the 3rd wk of development (Fig. 591-1*A*). Failure of normal induction is responsible for most of the NTDs, as well as disorders of prosencephalic development. Rapid growth of cells within the neural plate causes further invagination of the neural groove and differentiation of a conglomerate of cells, the neural crest, which migrate laterally on the surface of the neural tube (Fig. 591-1*B*). The notochordal plate becomes the centrally placed notochord, which acts as a foundation around which the vertebral column ultimately develops. With formation of the vertebral column, the notochord undergoes involution and becomes the nucleus pulposus of the intervertebral disks. The neural crest cells differentiate to form the peripheral nervous system, including the spinal and autonomic ganglia and the ganglia of cranial nerves V, VII, VIII, IX, and X. In addition, the neural crest forms the leptomeninges, as well as Schwann cells, which are responsible for myelination of the peripheral nervous system. The dura is thought to arise from the paraxial mesoderm. In the region of the embryo destined to become the head, similar patterns exist. In this region, the notochord is replaced by the prechordal mesoderm.

In the 3rd wk of embryonic development, invagination of the neural groove is completed and the neural tube is formed by separation from the overlying surface ectoderm (see Fig. 591-1*C*). Initial closure of the neural tube is accomplished in the area corresponding to the future junction of the spinal cord and medulla and moves rapidly both caudally and rostrally. For a brief period, the neural tube is open at both ends, and the neural canal communicates freely with the amniotic cavity (see Fig. 591-1*D*). Failure of closure of the neural tube allows excretion of fetal substances (α-fetoprotein [AFP], acetylcholinesterase) into the amniotic fluid, serving as biochemical markers for a NTD. Prenatal screening of maternal serum for AFP in the 16th-18th wk of gestation is an effective method for identifying pregnancies at risk for fetuses with NTDs in utero. Normally, the rostral end of the neural

tube closes on the 23rd day and the caudal neuropore closes by a process of secondary neurulation by the 27th day of development, before the time that many women realize they are pregnant.

The embryonic neural tube consists of 3 zones: ventricular, mantle, and marginal (see Fig. 591-1*E*). The ependymal layer consists of pluripotential, pseudostratified, columnar neuroepithelial cells. Specific neuroepithelial cells differentiate into primitive neurons or neuroblasts that form the mantle layer. The marginal zone is formed from cells in the outer layer of the neuroepithelium, which ultimately becomes the white matter. Glioblasts, which act as the primitive supportive cells of the CNS, also arise from the neuroepithelial cells in the ependymal zone. They migrate to the mantle and marginal zones and become future astrocytes and oligodendrocytes. The importance of other pathways of progenitor cell generation and migration are also being elucidated. It is likely that microglia originate from mesenchymal cells at a later stage of fetal development when blood vessels begin to penetrate the developing nervous system.

591.2 Spina Bifida Occulta (Occult Spinal Dysraphism)

Stephen L. Kinsman and Michael V. Johnston

Spina bifida occulta is a common anomaly consisting of a midline defect of the vertebral bodies without protrusion of the spinal cord or meninges. Most patients are asymptomatic and lack neurologic signs, and the condition is usually of no consequence. Some consider the term *spina bifida occulta* to denote merely a posterior vertebral body fusion defect. This simple defect does not have an associated spinal cord malformation. Other clinically more significant forms of this closed spinal cord malformation are more correctly termed *occult spinal dysraphism.* In most of these cases, there are cutaneous manifestations such as a hemangioma, discoloration of the skin, pit, lump, dermal sinus, or hairy patch (Fig. 591-2). A spine roentgenogram in simple spina bifida occulta shows a defect in closure of the posterior vertebral arches and laminae, typically involving L5 and S1; there is no abnormality of the meninges, spinal cord, or nerve roots. Occult spinal dysraphism is often associated with more significant developmental abnormalities of the spinal cord, including syringomyelia, diastematomyelia, lipoma, fatty filum, dermal sinus, and/or a tethered cord. A spine x-ray in these cases might show bone defects or may be normal. All cases of occult spinal dysraphism are best investigated with MRI (Fig. 591-3). Initial screening in the neonate may include ultrasonography, but MRI is more accurate at any age.

A dermoid sinus usually forms a small skin opening, which leads into a narrow duct, sometimes indicated by protruding hairs, a hairy patch, or a vascular nevus. Dermoid sinuses occur in the midline at the sites where meningoceles or encephaloceles can occur: the lumbosacral region or occiput, respectively and occasionally in the cervical or thoracic area. Dermoid sinus tracts can pass through the dura, acting as a conduit for the spread of infection. Recurrent meningitis of occult origin should prompt careful examination for a small sinus tract in the posterior midline region, including the back of the head. Lower back sinuses are usually above the gluteal fold and are directed cephalad. Tethered spinal cord syndrome may also be an associated problem. Diastematomyelia commonly has bony abnormalities that require surgical intervention along with untethering of the spinal cord.

An approach to imaging of the spine in patients with cutaneous lesions is noted in Table 591-1.

Table 591-1	Cutaneous Lesions Associated with Occult Spinal Dysraphism
IMAGING INDICATED Subcutaneous mass or lipoma Hairy patch Dermal sinus Atypical dimples (deep, >5 mm, >25 mm from anal verge) Vascular lesion, e.g., hemangioma or telangiectasia Skin appendages or polypoid lesions, e.g., skin tags, tail-like appendages Scar-like lesions	
IMAGING UNCERTAIN Hyperpigmented patches Deviation of the gluteal fold	
IMAGING NOT REQUIRED Simple dimples (<5 mm, <25 mm from anal verge) Coccygeal pits

591.3 Meningocele

Stephen L. Kinsman and Michael V. Johnston

A meningocele is formed when the meninges herniate through a defect in the posterior vertebral arches or the anterior sacrum. The spinal cord is usually normal and assumes a normal position in the spinal canal, although there may be tethering of the cord, syringomyelia, or diastematomyelia. A fluctuant midline mass that might transilluminate occurs along the vertebral column, usually in the lower back. Most meningoceles are well covered with skin and pose no immediate threat to the patient. Careful neurologic examination is mandatory. Orthopedic and urologic examination should also be considered. In asymptomatic children with normal neurologic findings and full-thickness skin covering the meningocele, surgery may be delayed or sometimes not performed.

Before surgical correction of the defect, the patient must be thoroughly examined with the use of plain x-rays, ultrasonography, and MRI to determine the extent of neural tissue involvement, if any, and associated anomalies, including diastematomyelia, lipoma, and possible clinically significant tethered spinal cord. Urologic evaluation usually includes cystometrogram to identify children with neurogenic bladder who are at risk for renal deterioration. Patients with leaking cerebrospinal fluid (CSF) or a thin skin covering should undergo immediate surgical treatment to prevent meningitis. A CT scan or MRI of the head is recommended for children with a meningocele because of the association with hydrocephalus in some cases. An anterior meningocele projects into the pelvis through a defect in the sacrum. Symptoms of constipation and bladder dysfunction develop due to the increasing size of the lesion. Female patients might have associated anomalies of the genital tract, including a rectovaginal fistula and vaginal septa. Plain x-rays demonstrate a defect in the sacrum, and CT scanning or MRI outlines the extent of the meningocele and any associated anomalies.

591.4 Myelomeningocele

Stephen L. Kinsman and Michael V. Johnston

Myelomeningocele represents the most severe form of dysraphism, a so-called aperta or open form, involving the vertebral column and spinal cord, which occurs with an incidence of approximately 1 in 4,000 live births.

ETIOLOGY

The cause of myelomeningocele is unknown, but as with all neural tube closure defects, including anencephaly, a genetic predisposition exists; the risk of recurrence after 1 affected child is 3-4% and increases to 10% with 2 prior affected children. Both epidemiologic evidence and the presence of substantial familial aggregation of anencephaly, myelomeningocele, and craniorachischisis indicate heredity, on a polygenic basis, as a significant contributor to the etiology of NTDs. Nutritional and environmental factors have a role in the etiology of myelomeningocele as well.

Folate is intricately involved in the prevention and etiology of NTDs. Folate functions in single-carbon transfer reactions and exists in many chemical forms. Folic acid (pteroylmonoglutamic acid), which is the most oxidized and stable form of folate, occurs rarely in food but is the form used in vitamin supplements and in fortified food products, particularly flour. Most naturally occurring folates (food folate) are pteroylpolyglutamates, which contain 1-6 additional glutamate molecules joined in a peptide linkage to the γ-carboxyl of glutamate. Folate coenzymes are involved in DNA synthesis, purine synthesis, generation of formate into the formate pool, and amino acid interconversion; the conversion of homocysteine to methionine provides methionine for the synthesis of *S*-adenosylmethionine (SAMe, an agent important for in vivo methylation). Mutations in the genes encoding the enzymes involved in homocysteine metabolism may play a role in the pathogenesis of meningomyelocele. These enzymes include 5,10-methylenetetrahydrofolate reductase, cystathionine β-synthase, and methionine synthase. An association between a thermolabile variant of 5,10-methylenetetrahydrofolate reductase and mothers of children with NTDs might account for up to 15% of preventable NTDs. Maternal periconceptional use of folic acid supplementation reduces the incidence of NTDs in pregnancies at risk by at least 50%. To be effective, folic acid supplementation should be initiated before conception and continued until at least the 12th wk of gestation, when neurulation is complete. The mechanisms by which folic acid prevents NTDs remain poorly understood.

PREVENTION

The U.S. Public Health Service has recommended that all women of childbearing age and who are capable of becoming pregnant take 0.4 mg of folic acid daily. If, however, a pregnancy is planned in high-risk women (previously affected child), supplementation should be started with 4 mg of folic acid daily, beginning 1 mo before the time of the planned conception. The modern diet provides about half the daily requirement of folic acid. To increase folic acid intake, fortification of flour, pasta, rice, and cornmeal with 0.15 mg folic acid per 100 g was mandated in the United States and Canada in 1998. The added folic acid is insufficient to maximize the prevention of preventable NTDs. Therefore, informative educational programs and folic acid vitamin supplementation remain essential for women planning a pregnancy and possibly for all women of childbearing age. In addition, women should also strive to consume food folate from a varied diet. Certain drugs, including drugs that antagonize folic acid, such as trimethoprim and the anticonvulsants carbamazepine, phenytoin, phenobarbital, and primidone, increase the risk of myelomeningocele. The anticonvulsant valproic acid causes NTDs in approximately 1-2% of pregnancies when administered during pregnancy. Some epilepsy clinicians recommend that all female patients of childbearing potential who take anticonvulsant medications also receive folic acid supplements. There may be a threshold for ideal red blood cell folate levels (900-1,000 nmol/L), which is associated with a markedly reduced risk of NTDs.

CLINICAL MANIFESTATIONS

Myelomeningocele produces dysfunction of many organs and structures, including the skeleton, skin, and gastrointestinal and genitourinary tracts, in addition to the peripheral nervous system and the CNS. A myelomeningocele may be located anywhere along the neuraxis, but the lumbosacral region accounts for at least 75% of the cases. The extent and degree of the neurologic deficit depend on the location of the myelomeningocele and the associated lesions. A lesion in the low sacral region causes bowel and bladder incontinence associated with anesthesia in the perineal area but with no impairment of motor function. Newborns with a defect in the midlumbar or high lumbothoracic region typically have either a sac-like cystic structure covered by a thin layer of partially epithelialized tissue (Fig. 591-4) or an exposed flat

Figure 591-4 A lumbar myelomeningocele is covered by a thin layer of skin.

neural placode without overlying tissues. When a cyst or membrane is present, remnants of neural tissue are visible beneath the membrane, which occasionally ruptures and leaks CSF.

Examination of the infant shows a flaccid paralysis of the lower extremities, an absence of deep tendon reflexes, a lack of response to touch and pain, and a high incidence of lower-extremity deformities (clubfeet, ankle and/or knee contractures, and subluxation of the hips). Some children have constant urinary dribbling and a relaxed anal sphincter. Other children do not leak urine and in fact have a high-pressure bladder and sphincter dyssynergy. Thus, a myelomeningocele above the midlumbar region tends to produce lower motor neuron signs because of abnormalities and disruption of the conus medullaris and above spinal cord structures.

Infants with myelomeningocele typically have increased neurologic deficit as the myelomeningocele extends higher into the thoracic region. These infants sometimes have an associated kyphotic gibbus that requires neonatal orthopedic correction. Patients with a myelomeningocele in the upper thoracic or cervical region usually have a very minimal neurologic deficit and, in most cases, do not have hydrocephalus. They can have neurogenic bladder and bowel.

Hydrocephalus in association with a type II Chiari malformation develops in at least 80% of patients with myelomeningocele. Generally, patients with sacral myelomeningocele have a very low risk of hydrocephalus. The possibility of hydrocephalus developing after the neonatal period should always be considered, no matter what the spinal level. Ventricular enlargement may be indolent and slow growing or may be rapid causing a bulging anterior fontanel, dilated scalp veins, setting-sun appearance of the eyes, irritability, and vomiting in association with an increased head circumference. Approximately 15% of infants with hydrocephalus and Chiari II malformation develop symptoms of hindbrain (brainstem) dysfunction, including difficulty feeding, choking, stridor, apnea, vocal cord paralysis, pooling of secretions, and spasticity of the upper extremities, which, if untreated, can lead to death. This Chiari crisis is caused by downward herniation of the medulla and cerebellar tonsils through the foramen magnum, as well as endogenous malformations in the cerebellum and brainstem, causing dysfunction.

TREATMENT

Management and supervision of a child and family with a myelomeningocele require a multidisciplinary team approach, including surgeons, other physicians, and therapists, with 1 individual (often a pediatrician) acting as the advocate and coordinator of the treatment program. The news that a newborn child has a devastating condition such as myelomeningocele causes parents to feel considerable grief and anger. They need time to learn about the condition and its associated complications and to reflect on the various procedures and treatment plans. A knowledgeable individual in an unhurried and nonthreatening setting must give the parents the facts, along with general prognostic information and management strategies and timelines. If possible, discussions with other parents of children with NTDs are helpful in resolving important questions and issues.

Surgery is often done within a day or so of birth but can be delayed for several days (except when there is a CSF leak) to allow the parents time to begin to adjust to the shock and to prepare for the multiple procedures and inevitable problems that lie ahead. Evaluation of other congenital anomalies and renal function can also be initiated before surgery. Most pediatric centers aggressively treat the majority of infants with myelomeningocele. After repair of a myelomeningocele, most infants require a shunting procedure for hydrocephalus. If symptoms or signs of hindbrain dysfunction appear, early surgical decompression of the posterior fossa is indicated. Clubfeet can require taping or casting, and dislocated hips may require operative procedures.

Careful evaluation and reassessment of the genitourinary system are some of the most important components of the management. Teaching the parents, and, ultimately, the patient, to regularly catheterize a neurogenic bladder is a crucial step in maintaining a low residual volume and bladder pressure that prevents urinary tract infections and reflux leading to pyelonephritis, hydronephrosis, and bladder damage. Latex-free catheters and gloves must be used to prevent development of latex allergy. Periodic urine cultures and assessment of renal function, including serum electrolytes and creatinine as well as renal scans, vesiculourethrograms, renal ultrasonography, and cystometrograms, are obtained according to the risk status and progress of the patient and the results of the physical examination. This approach to urinary tract management has greatly reduced the need for urologic diversionary procedures and significantly decreased the morbidity and mortality associated with progressive renal disease in these patients. Some children can become continent with surgical implantation of an artificial urinary sphincter (these are used less often) or bladder augmentation at a later age.

Although incontinence of fecal matter is common and is socially unacceptable during the school years, it does not pose the same organ-damaging risks as urinary dysfunction, but occasionally fecal impaction and/or megacolon develop. Many children can be bowel-trained with a regimen of timed enemas or suppositories that allows evacuation at a predetermined time once or twice a day. Special attention to low anorectal tone and enema administration and retention is often required. Appendicostomy for antegrade enemas may also be helpful (see Chapter 23.4).

Functional ambulation is the wish of each child and parent and may be possible, depending on the level of the lesion and on intact function of the iliopsoas muscles. Almost every child with a sacral or lumbosacral lesion obtains functional ambulation; approximately half the children with higher defects ambulate with the use of braces, other orthotic devices, and canes. Ambulation is often more difficult as adolescence approaches and body mass increases. Deterioration of ambulatory function, particularly during earlier years, should prompt referral for evaluation of tethered spinal cord and other neurosurgical issues.

In utero surgical closure of a spinal lesion has been successful in a few centers. Preliminary reports suggest a lower incidence of hindbrain abnormalities and hydrocephalus (fewer shunts) as well as improved motor outcomes. This suggests that the defects may be progressive in utero and that prenatal closure might prevent the development of further loss of function. In utero diagnosis is facilitated by maternal serum AFP screening and by fetal ultrasonography (see Chapter 96).

PROGNOSIS

For a child who is born with a myelomeningocele and who is treated aggressively, the mortality rate is 10-15%, and most deaths occur before age 4 yr, although life-threatening complications occur at all ages. At least 70% of survivors have normal intelligence, but learning problems and seizure disorders are more common than in the general population. Previous episodes of meningitis or ventriculitis adversely affect intellectual and cognitive function. Because myelomeningocele is a chronic disabling condition, periodic and consistent multidisciplinary follow-up is required for life. Renal dysfunction is one of the most important determinants of mortality.

591.5 Encephalocele

Stephen L. Kinsman and Michael V. Johnston

Two major forms of dysraphism affect the skull, resulting in protrusion of tissue through a bony midline defect, called cranium bifidum. A cranial meningocele consists of a CSF-filled meningeal sac only, and a cranial encephalocele contains the sac plus cerebral cortex, cerebellum, or portions of the brainstem. Microscopic examination of the neural tissue within an encephalocele often reveals abnormalities. The cranial defect occurs most commonly in the occipital region at or

below the inion, but in certain parts of the world, frontal or nasofrontal encephaloceles (transethmoidal, sphenoethmoidal, sphenomaxillary, sphenoorbital, transsphenoidal) are more common. Some frontal lesions are associated with a cleft lip and palate. These abnormalities are one-tenth as common as neural tube closure defects involving the spine. The etiology is presumed to be similar to that for anencephaly and myelomeningocele; examples of each are reported in the same family.

Infants with a cranial encephalocele are at increased risk for developing hydrocephalus because of **aqueductal stenosis**, **Chiari malformation**, or the **Dandy-Walker syndrome**. Examination might show a small sac with a pedunculated stalk or a large cyst-like structure that can exceed the size of the cranium. The lesion may be completely covered with skin, but areas of denuded lesion can occur and require urgent surgical management. Transillumination of the sac can indicate the presence of neural tissue. A plain x-ray of the skull and cervical spine is indicated to define the anatomy of the cranium and vertebrae. Ultrasonography is most helpful in determining the contents of the sac. MRI or CT further helps define the spectrum of the lesion. Children with a cranial meningocele generally have a good prognosis, whereas patients with an encephalocele are at risk for vision problems, microcephaly, intellectual disability, and seizures. Generally, children with neural tissue within the sac and associated hydrocephalus have the poorest prognosis.

Cranial encephalocele is often part of a syndrome. Meckel-Gruber syndrome is a rare autosomal recessive condition that is characterized by an occipital encephalocele, cleft lip or palate, microcephaly, microphthalmia, abnormal genitalia, polycystic kidneys, and polydactyly. Determination of maternal serum AFP levels and ultrasound measurement of the biparietal diameter, as well as identification of the encephalocele itself, can diagnose encephaloceles in utero. Fetal MRI can help define the extent of associated CNS anomalies and the degree of brain herniated into the encephalocele.

Bibliography is available at Expert Consult.

591.6 Anencephaly

Stephen L. Kinsman and Michael V. Johnston

An anencephalic infant presents a distinctive appearance with a large defect of the calvarium, meninges, and scalp associated with a rudimentary brain, which results from failure of closure of the rostral neuropore, the opening of the anterior neural tube. The primitive brain consists of portions of connective tissue, vessels, and neuroglia. The cerebral hemispheres and cerebellum are usually absent, and only a residue of the brainstem can be identified. The pituitary gland is hypoplastic, and the spinal cord pyramidal tracts are missing owing to the absence of the cerebral cortex. Additional anomalies include folding of the ears, cleft palate, and congenital heart defects in 10-20% of cases. Most anencephalic infants die within several days of birth.

The incidence of anencephaly approximates 1 in 1,000 live births; the greatest incidence is in Ireland, Wales, and Northern China. The recurrence risk is approximately 4% and increases to 10% if a couple has had 2 previously affected pregnancies. Many factors, in addition to genetics, are implicated as a cause of anencephaly, including low socioeconomic status, nutritional and vitamin deficiencies, and a large number of environmental and toxic factors. It is very likely that several noxious stimuli interact on a genetically susceptible host to produce anencephaly. The incidence of anencephaly has been decreasing since the 1990s. Approximately 50% of cases of anencephaly have associated polyhydramnios. Couples who have had an anencephalic infant should have successive pregnancies monitored, including amniocentesis, determination of AFP levels, and ultrasound examination between the 14th and 16th wk of gestation. Prenatal folic acid supplementation decreases the risk of this condition.

591.7 Disorders of Neuronal Migration

Stephen L. Kinsman and Michael V. Johnston

Disorders of neuronal migration can result in minor abnormalities with little or no clinical consequence (small heterotopia of neurons) or devastating abnormalities of CNS structure and/or function (intellectual disability, seizures, lissencephaly, and schizencephaly, particularly the open-lip form) (Fig. 591-5). One of the most important mechanisms in the control of neuronal migration is the radial glial fiber system that guides neurons to their proper site. Migrating neurons attach to the radial glial fiber and then disembark at predetermined sites to form, ultimately, the precisely designed 6-layered cerebral cortex. Another important mechanism is the tangential migration of progenitor neurons destined to become cortical interneurons. The severity and the extent of the disorder are related to numerous factors, including the timing of a particular insult and a host of environmental and genetic contributors. Some cortical malformations may be from somatic mutations, as exemplified by kinesin gene mutations in patients with pachygyria.

LISSENCEPHALY

Lissencephaly, or agyria, is a rare disorder that is characterized by the absence of cerebral convolutions and a poorly formed sylvian fissure, giving the appearance of a 3-4 mo fetal brain. The condition is probably a result of faulty neuroblast migration during early embryonic life and is usually associated with enlarged lateral ventricles and heterotopias in the white matter. In some forms, there is a 4-layered cortex, rather than the usual 6-layered one, with a thin rim of periventricular white matter and numerous gray heterotopias visible by microscopic examination. Milder forms of lissencephaly also exist.

Figure 591-5 T1-weighted MRI scan demonstrating band heterotopia. A thin layer of white matter *(black arrow)* lies between the band of heterotopic gray matter and the cortical surface. Failure of cortical organization with lissencephaly is present in both frontal lobes *(white arrow)*.

These infants present with failure to thrive, microcephaly, marked developmental delay, and a severe seizure disorder. Ocular abnormalities are common, including hypoplasia of the optic nerve and microphthalmia. Lissencephaly can occur as an isolated finding, but it is associated with Miller-Dieker syndrome in approximately 15% of cases. These children have characteristic facies, including a prominent forehead, bitemporal hollowing, anteverted nostrils, a prominent upper lip, and micrognathia. Approximately 70% of children with Miller-Dieker syndrome have visible or submicroscopic chromosomal deletions of 17p13.3.

The gene *LIS-1* (lissencephaly 1) that maps to chromosome region 17p13.3 is deleted in patients with Miller-Dieker syndrome. CT and MRI scans typically show a smooth brain with an absence of sulci (Fig. 591-6). *Doublecortin* is an X chromosome gene that causes lissencephaly when mutated in males and subcortical band heterotopia when mutated in females. Other important forms of lissencephaly include the Walker-Warburg variant and other cobblestone cortical malformations.

SCHIZENCEPHALY

Schizencephaly is the presence of unilateral or bilateral clefts within the cerebral hemispheres owing to an abnormality of morphogenesis (Fig. 591-7). The cleft may be fused or unfused and, if unilateral and large, may be confused with a porencephalic cyst. Not infrequently, the borders of the cleft are surrounded by abnormal brain, particularly microgyria. MRI is the study of choice for elucidating schizencephaly and associated malformations.

When the clefts are bilateral, many patients are severely intellectually challenged, with seizures that are difficult to control, and microcephalic, with spastic quadriparesis. Some cases of bilateral schizencephaly are associated with septooptic dysplasia and endocrinologic disorders. Unilateral schizencephaly is a common cause of congenital hemiparesis. It remains controversial whether genetic causes of schizencephaly exist. Some gene mutations are seen in cases of familial schizencephaly.

NEURONAL HETEROTOPIAS

Subtypes of neuronal heterotopias include periventricular nodular heterotopias, subcortical heterotopia (including band-type), and marginal glioneuronal heterotopias. Intractable seizures are a common feature. Several genes have been identified that are a cause of these conditions.

POLYMICROGYRIAS

Polymicrogyria is characterized by an augmentation of small convolutions separated by shallow enlarged sulci. Epilepsy, including drug-resistant forms, is a common feature. Truncation of the *KBP* gene has been implicated in a family with multiple members with polymicrogyria.

Figure 591-6 MRI of an infant with lissencephaly. Note the absence of cerebral sulci and the maldeveloped sylvian fissures associated with enlarged ventricles.

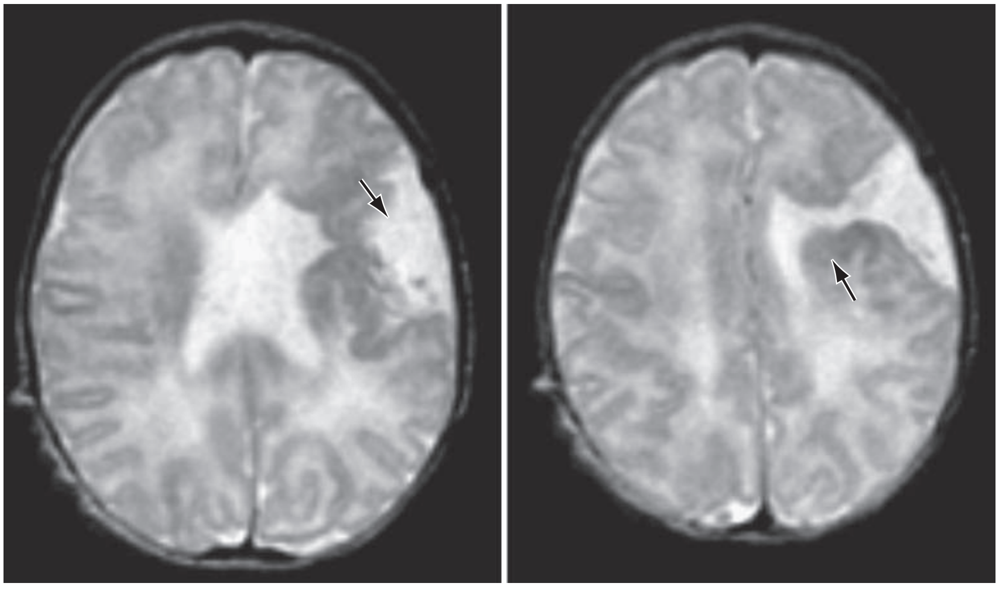

Figure 591-7 Unilateral schizencephaly shown on axial MR images of the brain. Example of an open-lip schizencephaly with a cleft communicating between the ventricle and the extraaxial cranial space *(arrow on left panel)*. Many of these clefts are lined with abnormal gray matter *(arrow on right panel)*.

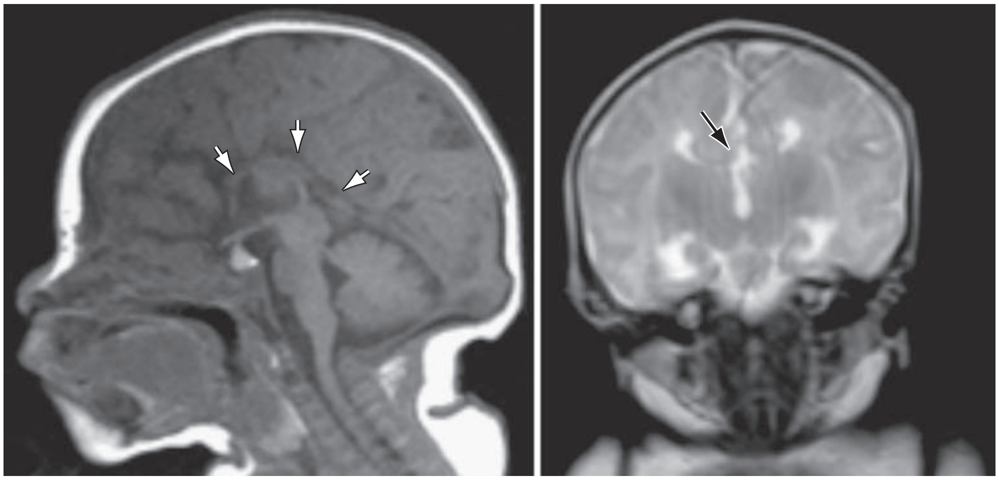

Figure 591-8 Agenesis of the corpus callosum shown on MR images of the brain. Sagittal *(left panel)* and coronal *(right panel)* views of an infant show the total absence of a midsagittal white matter structure *(left panel, arrows)*. The coronal view *(right panel)* demonstrates (despite some motion artifact) the absence of a structure bridging the 2 hemispheres *(area under arrow)*.

FOCAL CORTICAL DYSPLASIAS

Focal cortical dysplasias consist of abnormal cortical lamination in a discrete area of cortex. High-resolution, thin-section MRI can reveal these areas sometimes in the setting of drug-resistant epilepsy.

PORENCEPHALY

Porencephaly is the presence of cysts or cavities within the brain that result from developmental defects or acquired lesions, including infarction of tissue. True porencephalic cysts are most commonly located in the region of the sylvian fissure and typically communicate with the subarachnoid space, the ventricular system, or both. They represent developmental abnormalities of cell migration and are often associated with other malformations of the brain, including microcephaly, abnormal patterns of adjacent gyri, and encephalocele. Affected infants tend to have many problems, including intellectual disability, spastic hemiparesis or quadriparesis, optic atrophy, and seizures.

Several risk factors for porencephalic cyst formation have been identified, including hemorrhagic venous infarctions; various thrombophilias such as protein C deficiency and factor V Leiden mutations; perinatal alloimmune thrombocytopenia; von Willebrand disease; maternal warfarin use; maternal cocaine use; congenital infections; trauma such as amniocentesis; and maternal abdominal trauma. Mutations in the *COL4A1* gene have been described in cases of familial porencephaly.

Pseudoporencephalic cysts characteristically develop during the perinatal or postnatal period and result from abnormalities (infarction, hemorrhage) of arterial or venous circulation. These cysts tend to be unilateral, do not communicate with a fluid-filled cavity, and are not associated with abnormalities of cell migration or CNS malformations. Infants with pseudoporencephalic cysts present with hemiparesis and focal seizures in the 1st yr of life and sometimes present with neonatal encephalopathy or as a floppy newborn or infant.

591.8 Agenesis of the Corpus Callosum

Stephen L. Kinsman and Michael V. Johnston

Agenesis of the corpus callosum consists of a heterogeneous group of disorders that vary in expression from severe intellectual and neurologic abnormalities to the asymptomatic and normally intelligent patient (Fig. 591-8). The corpus callosum develops from the commissural plate that lies in proximity to the anterior neuropore. Either a direct insult to the commissural plate or disruption of the genetic signaling that specifies and organizes this area during early embryogenesis causes agenesis of the corpus callosum.

It is often said that the outcome of agenesis of the corpus callosum is dictated by *the company it keeps*. When agenesis of the corpus callosum is an isolated phenomenon, the patient may be normal. When it is accompanied by brain anomalies from cell migration defects, such as heterotopias, polymicrogyria, and pachygyria (broad, wide gyri), patients often have significant neurologic abnormalities, including intellectual disability, microcephaly, hemiparesis, diplegia, and seizures.

The anatomic features of agenesis of the corpus callosum are best depicted on MRI or CT scan and include widely separated frontal horns with an abnormally high position of the third ventricle between the lateral ventricles. MRI precisely outlines the extent of the corpus callosum defect.

Absence of the corpus callosum may be inherited as an X-linked recessive trait or as an autosomal dominant trait and on occasion as an autosomal recessive trait. The condition may be associated with specific chromosomal disorders, particularly trisomy 8 and trisomy 18. Single-gene mutations have also been identified, usually in association with other anomalies. Agenesis of the corpus callosum is also seen in some metabolic disorders (Table 591-2).

Aicardi syndrome represents a complex disorder that affects many systems and is typically associated with agenesis of the corpus callosum, distinctive chorioretinal lacunae, and infantile spasms. Patients are almost all female, suggesting a genetic abnormality of the X chromosome (it may be lethal in males during fetal life). Seizures become evident during the 1st few mo and are typically resistant to anticonvulsants. An electroencephalogram shows independent activity recorded from both hemispheres as a result of the absent corpus callosum and shows often hemihypsarrhythmia. All patients have severe intellectual disability and can have abnormal vertebrae that may be fused or only partially developed (hemivertebra). Abnormalities of the retina, including circumscribed pits or lacunae and coloboma of the optic disc, are the most characteristic findings of Aicardi syndrome.

Colpocephaly refers to an abnormal enlargement of the occipital horns of the ventricular system and can be identified as early as the fetal period. It is often associated with agenesis of the corpus callosum, but it can occur in isolation. It is also associated with microcephaly. It can also be seen in anatomic megalencephaly, such as is associated with Sotos syndrome.

HOLOPROSENCEPHALY

Holoprosencephaly is a developmental disorder of the brain that results from defective formation of the prosencephalon and

Table 591-2 Disorders Associated with Agenesis of the Corpus Callosum*

DISORDER	SALIENT FEATURES
WITH IDENTIFIED GENES†	
Andermann syndrome (*KCC3*)	ACC, progressive neuropathy, and dementia
Donnai-Barrow syndrome (*LRP2*)	Diaphragmatic hernia, exomphalos, ACC, deafness
Frontonasal dysplasia (*ALX1*)	ACC, bilateral extreme microphthalmia, bilateral oblique facial cleft
XLAG (*ARX*)	Lissencephaly, ACC, intractable epilepsy
Microcephaly (*TBR2*)	ACC, polymicrogyria
Microcephaly with simplified gyral pattern and ACC (*WDR62*)	
Mowat-Wilson syndrome (*ZFHX1B*)	Hirschsprung disease, ACC
Pyridoxine-dependent epilepsy (*ALDH7A1*)	ACC, seizures, other brain malformations
Pyruvate dehydrogenase deficiency (*PDHA1, PDHB, PDHX*)	ACC with other brain changes
ACC with fatal lactic acidosis (*MRPS16*)	Complexes I and IV deficiency, ACC, brain malformations
HSAS/MASA syndromes (*L1CAM*)	Hydrocephalus, adducted thumbs, ACC, MR
ACC SEEN CONSISTENTLY (NO GENE YET IDENTIFIED)	
Acrocallosal syndrome	ACC, polydactyly, craniofacial changes, MR
Aicardi syndrome	ACC, chorioretinal lacunae, infantile spasms, MR
Chudley-McCullough syndrome	Hearing loss, hydrocephalus, ACC, colpocephaly
FG syndrome	MR, ACC, craniofacial changes, macrocephaly
Genitopatellar syndrome	Absent patellae, urogenital malformations, ACC
Temtamy syndrome	ACC, optic coloboma, craniofacial changes, MR
Toriello-Carey syndrome	ACC, craniofacial changes, cardiac defects, MR
Vici syndrome	ACC, albinism, recurrent infections, MR
ACC SEEN OCCASIONALLY (PARTIAL LIST)‡	
ACC with spastic paraparesis (*SPG11; SPG15*)	Progressive spasticity and neuropathy, thin corpus callosum
Craniofrontonasal syndrome	Coronal craniosynostosis, facial asymmetry, bifid nose
Fryns syndrome	CDH, pulmonary hypoplasia, craniofacial changes
Marden-Walker syndrome	Blepharophimosis, micrognathia, contractures, ACC
Meckel-Gruber syndrome	Encephalocele, polydactyly, polycystic kidneys
Nonketotic hyperglycinemia (*GLDC, GCST, GCSH*)	ACC, cerebral and cerebellar atrophy, myoclonus, progressive encephalopathy
Microphthalmia with linear skin defects	Microphthalmia, linear skin markings, seizures
Opitz G syndrome	Pharyngeal cleft, craniofacial changes, ACC, MR
Orofaciodigital syndrome	Tongue hamartoma, microretrognathia, clinodactyly
Pyruvate decarboxylase deficiency	Lactic acidosis, seizures, severe MR and spasticity
Rubinstein-Taybi syndrome	Broad thumbs and great toes, MR, microcephaly
Septooptic dysplasia (de Morsier syndrome)	Hypoplasia of septum pellucidum and optic chiasm
Sotos syndrome	Physical overgrowth, MR, craniofacial changes
Warburg micro syndrome	Microcephaly, microphthalmia, microgenitalia, MR
Wolf-Hirschhorn syndrome	Microcephaly, seizures, cardiac defects, 4p–

*Reliable incidence data are unavailable for these very rare syndromes.
†Gene symbols in parentheses.
‡Many of these also may consistently have a thin of dysplastic corpus callosum, such as Sotos' syndrome or agenesis of the corpus callosum (ACC) with spastic paraparesis (SPG11). The overlap between ACC and these conditions is still under investigation. Other gene symbols are omitted from this section.
4p–, deletion of the terminal region of the short arm of chromosome 4, defines the genotype for Wolf-Hirschhorn patients; ACC, agenesis of the corpus callosum; ARX, Aristaless-related homeobox gene; CDH, congenital diaphragmatic hernia; HSAS/MASA, X-linked hydrocephalus/mental retardation, aphasia, shuffling gait, and adducted thumbs; KCC3, KCl cotransporter 3; L1CAM, L1 cell adhesion molecule; MR, mental retardation; MRPS16, mitochondrial ribosomal protein S16; SPG11, spastic paraplegia 11; XLAG, X-linked lissencephaly with absent corpus callosum and ambiguous genitalia; ZFHX1B, zinc finger homeobox 1b.
From Sherr EH, Hahn JS: Disorders of forebrain development. In Swaiman KF, Ashwal S, Ferriero DM, Schor NF, editors: Swaiman's pediatric neurology, *5th ed. Philadelphia, 2012, WB Saunders, Table 23-2.*

inadequate induction of forebrain structures. The abnormality, which represents a spectrum of severity, is classified into 3 groups: alobar, semilobar, and lobar, depending on the degree of the cleavage abnormality (Fig. 591-9). A fourth type, the middle interhemispheric fusion variant or syntelencephaly, involves a segmental area of noncleavage, actually a nonseparation, of the posterior frontal and parietal lobes. Facial abnormalities, including cyclopia, synophthalmia, cebocephaly, single nostril, choanal atresia, solitary central incisor tooth, and premaxillary agenesis are common in severe cases, because the prechordal mesoderm that induces the ventral prosencephalon is also responsible for induction of the median facial structures. Milder facial abnormalities are seen in milder forms. Alobar holoprosencephaly is characterized by a single ventricle, an absent falx, and nonseparated deep cerebral nuclei. Care must be taken not to overdiagnose holoprosencephaly based on ventricular abnormalities alone. Evidence of nonseparated midline deep-brain structures, such as caudate, putamen, globus pallidus, and hypothalamus, is the critical element for diagnosis.

Affected children with the alobar type have high mortality rates, but some live for years. Mortality and morbidity with milder types are more variable, and morbidity is less severe. Care must be taken not to prognosticate severe outcomes in all cases. The incidence of holoprosencephaly ranges from 1 in 5,000-16,000 live births. A prenatal diagnosis can be confirmed by ultrasonography after the 10th wk of gestation for more severe types, but fetal MRI at later gestational ages gives far greater anatomic, and therefore diagnostic, precision.

The cause of holoprosencephaly is often not identified. There appears to be an association with maternal diabetes. Chromosomal abnormalities, including deletions of chromosomes 7q and 3p, 21q, 2p, 18p, and 13q, as well as trisomy 13 and 18, account for upwards of 50% of all cases. Mutations in the *sonic hedgehog* gene at 7q have been shown to cause holoprosencephaly. *Gene Reviews* lists 14 single-gene causes. Clinically, it is important to look for associated anomalies, because many syndromes are associated with holoprosencephaly.

591.9 Agenesis of the Cranial Nerves and Dysgenesis of the Posterior Fossa

Stephen L. Kinsman and Michael V. Johnston

Classification of disorders of cranial nerve, brainstem, and cerebellum development remains anatomic, but future classification systems will likely be based on the molecular biology of brain development based on the genes involved and the roles they play in orchestrating brain architecture.

CONGENITAL CRANIAL DYSINNERVATION DISORDERS

Absence of the cranial nerves or the corresponding central nuclei has been described in several conditions and includes the optic nerve defects, congenital ptosis, Marcus Gunn phenomenon (sucking jaw movements causing simultaneous eyelid blinking; this congenital synkinesis results from abnormal innervation of the trigeminal and oculomotor nerves), trigeminal and auditory nerves defects, and cranial nerves IX, X, XI, and XII defects. Increased understanding of these disorders and their genetic causes has led to the term *congenital cranial dysinnervation disorders*.

Optic nerve hypoplasia can occur in isolation or as part of the septooptic dysplasia complex (de Morsier syndrome). Septooptic dysplasia can be caused by a mutation in the *HESX1* gene.

Möbius syndrome is characterized by bilateral facial weakness, which is often associated with paralysis of the abducens nerve. Hypoplasia or agenesis of brainstem nuclei, as well as absent or decreased numbers of muscle fibers, has been reported. Affected infants present in the newborn period with facial weakness, causing feeding difficulties owing to a poor suck. The immobile, dull facies might give the incorrect impression of intellectual impairment; the prognosis for normal development is excellent in most cases. The facial appearance of Möbius syndrome has been improved by facial surgery.

Duane retraction syndrome is characterized by congenital limitation of horizontal globe movement and some globe retraction on attempted adduction and is believed to be the result of abnormal innervation by the oculomotor nerve of the lateral rectus muscle. Abnormalities of cranial nerve development have been demonstrated in this condition.

Less common than Duane retraction syndrome and Möbius syndrome are the group of disorders known as **congenital fibrosis of the extraocular muscles**. Congenital fibrosis of the extraocular muscles is characterized by severe restriction of eye movements and ptosis from abnormal oculomotor and trochlear nerve development and/or from abnormalities of extraocular muscle innervation.

BRAINSTEM AND CEREBELLAR DISORDERS

Disorders of the posterior fossa structures include abnormalities of not only the brainstem and cerebellum, but also the CSF spaces. Commonly encountered malformations include Chiari malformation, Dandy-Walker malformation, arachnoid cysts, mega cisterna magna, persisting Blake pouch, Joubert syndrome, rhombencephalosynapsis, Lhermitte-Duclos disease, and the pontocerebellar hypoplasias.

Chiari malformation is the most common malformation of the posterior fossa and hindbrain. It consists of herniation of the cerebellar tonsils though the foramen magnum. Often, there is also an associated developmental abnormality of the bones of the skull base leading to a small posterior fossa. Cases can be either asymptomatic or symptomatic. When symptoms develop, they often do not do so until late childhood. Symptoms include headaches that are worse with straining and other maneuvers that increase intracranial pressure. Symptoms of brainstem compression such as diplopia, oropharyngeal dysfunction, spasticity, tinnitus, and vertigo can occur. Obstructive hydrocephalus and/or syringomyelia can also occur.

Dandy-Walker malformation is part of a continuum of posterior fossa anomalies that include cystic dilation of the fourth ventricle, hypoplasia of the cerebellar vermis, hydrocephalus, and an enlarged posterior fossa with elevation of the lateral venous sinuses and the tentorium. Extracranial anomalies are also seen. Variable degrees of neurologic impairment are usually present. The etiology of Dandy-Walker malformation includes chromosomal abnormalities, single gene disorders, and exposure to teratogens.

Arachnoid cysts of the posterior fossa can be associated with hydrocephalus. Mega cisterna magna is characterized by an enlarged CSF space inferior and dorsal to the cerebellar vermis and when present in isolation may be considered a normal variant. Persisting Blake pouch is a cyst that obstructs the subarachnoid space and is associated with hydrocephalus.

Joubert syndrome is an autosomal recessive disorder (ciliopathy) with significant genetic heterogeneity that is associated with cerebellar vermis hypoplasia and the pontomesencephalic **molar tooth sign** (a deepening of the interpeduncular fossa with thick and straight superior cerebellar peduncles) (Fig. 591-10). It is associated with hypotonia, ataxia (as toddler), characteristic breathing abnormalities including episodic apnea and hyperpnea (which improves with age), global developmental delay, nystagmus, strabismus, ptosis, and oculomotor apraxia. There can be many associated systemic features (Joubert syndrome and related disorders) including progressive retinal dysplasia (Leber congenital amaurosis), coloboma, congenital heart disease, microcystic kidney disease, liver fibrosis, polydactyly, tongue protrusion, and soft tissue tumors of the tongue (Fig. 591-11).

Rhombencephalosynapsis is an absent or small vermis associated with a nonseparation or fusion of the deep midline cerebellar structures. Ventriculomegaly or hydrocephalus is often seen. There is variable clinical presentation from normal to cognitive and language impairments, epilepsy, and spasticity. **Lhermitte-Duclos** disease is a dysplastic gangliocytoma of the cerebellum leading to focal enlargement of the cerebellum and macrocephaly, cerebellar signs, and seizures.

Pontocerebellar hypoplasias are a group of disorders characterized by impairment of cerebellar and pontine development together with histopathologic features of neuronal death and glial replacement. Clinical features tend to be nonspecific and include hypotonia, feeding difficulties, developmental delay, and breathing difficulties. Classification, associations, and causes include type I (with features of anterior

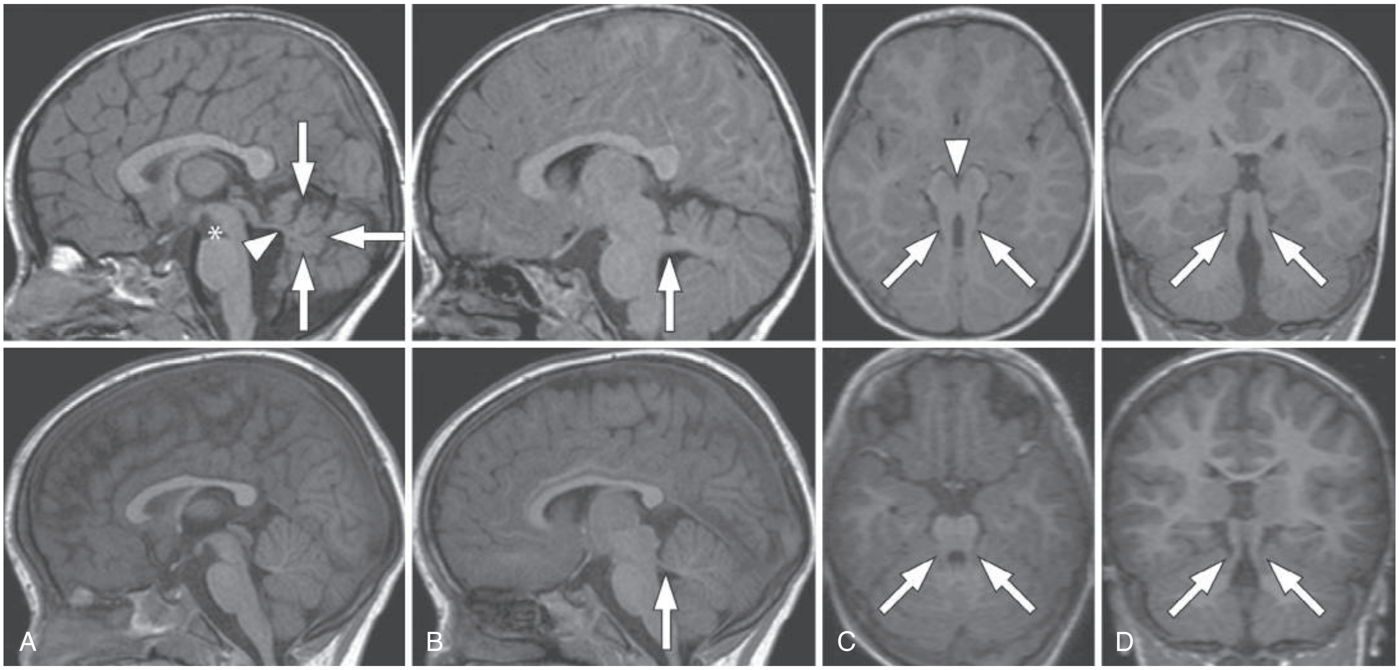

Figure 591-10 Neuroimaging findings in a 2-yr-old child with pure Joubert syndrome *(upper panels)* compared to a healthy control *(lower panels)*. **A,** Parasagittal T1-weighted image shows the thickened, elongated, and horizontally orientated superior cerebellar peduncles *(white arrow)*. **B,** Midsagittal T1-weighted image demonstrates a moderate hypoplasia and dysplasia of the cerebellar vermis *(white arrows)* with secondary distortion and enlargement of the fourth ventricle with rostral shifting of the fastigium *(white arrowhead)*. A deepened interpeduncular fossa is also noted. **C,** Axial T1-weighted image at the level of the pontomesencephalic junction shows the molar tooth sign with a deepened interpeduncular fossa *(white arrowhead)* and elongated, thickened, and horizontally orientated superior cerebellar peduncles *(white arrows)*. Additionally, the cerebellar vermis appears to be hypoplastic and its remnants dysplastic. **D,** Coronal T1-weighted image reveals the thickened superior cerebellar peduncles *(white arrows)*. *(From Romani M, Micalizzi A, Valente EM: Joubert syndrome: congenital cerebellar ataxia with the molar tooth.* Lancet Neurol *12:894–905, 2013, Fig. 1.)*

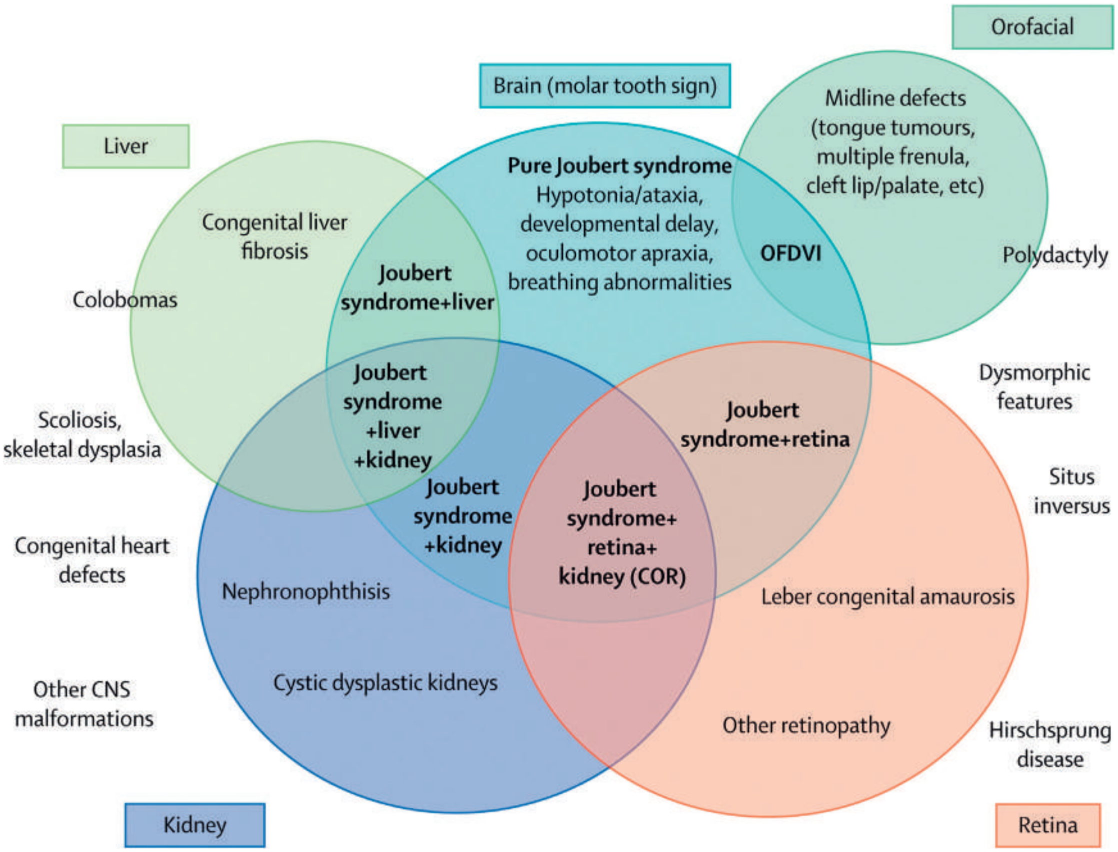

Figure 591-11 Spectrum of organ involvement in Joubert syndrome and classification in clinical subgroups *(in bold)*. Chorioretinal colobomas are more frequently found in the subgroup of Joubert syndrome with liver involvement but can be present also in other subgroups. Similarly, polydactyly (especially if preaxial or mesoaxial) is invariably present in the Orofaciodigital type VI subgroup, but postaxial polydactyly is frequently observed also in association with other Joubert syndrome phenotypes. Other clinical features outside the circles occur more rarely, without a specific association to a clinical subgroup. *CNS,* central nervous system; *COR,* cerebello oculorenal; K, kidney involvement; L, liver involvement; MTS, molar tooth sign; *OFDVI,* orofaciodigital type VI syndrome. *(From Romani M, Micalizzi A, Valente EM: Joubert syndrome: congenital cerebellar ataxia with the molar tooth.* Lancet Neurol *12:894–905, 2013, Fig. 3.)*

horn cell involvement), type II (with extrapyramidal features, seizures, and acquired microcephaly), Walker-Warburg syndrome, muscle-eye-brain disease, congenital disorders of glycosylation type 1A, mitochondrial cytopathies, teratogen exposure, congenital cytomegalovirus infection, 3-methylglutaconic aciduria, PEHO syndrome (progressive encephalopathy with edema, hypsarrhythmia, and optic atrophy), autosomal recessive cerebellar hypoplasia in the Hutterite population, lissencephaly with cerebellar hypoplasia, and other subtypes of pontocerebellar hypoplasia.

591.10 Microcephaly

Stephen L. Kinsman and Michael V. Johnston

Microcephaly is defined as a head circumference that measures more than 3 SD below the mean for age and sex. This condition is relatively common, particularly among developmentally delayed children. Although there are many causes of microcephaly, abnormalities in neuronal migration during fetal development, including heterotopias of neuronal cells and cytoarchitectural derangements, are often found. Microcephaly may be subdivided into 2 main groups: primary (genetic) microcephaly and secondary (nongenetic) microcephaly. A precise diagnosis is important for genetic counseling and for prediction for future pregnancies.

ETIOLOGY

Primary microcephaly refers to a group of conditions that usually have no associated malformations and follow a mendelian pattern of inheritance or are associated with a specific genetic syndrome. Affected infants are usually identified at birth because of a small head circumference. The more common types include familial and autosomal dominant microcephaly and a series of chromosomal syndromes that are summarized in Table 591-3. Primary microcephaly is also associated with at least 7 gene loci, and 7 single etiologic genes have been identified. It is known as autosomal recessive primary microcephaly and has autosomal inheritance. Many X-linked causes of microcephaly are caused by gene mutations that lead to severe structural brain

Table 591-3 Causes of Microcephaly

CAUSES	CHARACTERISTIC FINDINGS
PRIMARY (GENETIC)	
Familial (autosomal recessive)	Incidence 1 in 40,000 live births Typical appearance with slanted forehead, prominent nose and ears; severe mental retardation and prominent seizures; surface convolutional markings of the brain, poorly differentiated and disorganized cytoarchitecture
Autosomal dominant	Nondistinctive facies, upslanting palpebral fissures, mild forehead slanting, and prominent ears Normal linear growth, seizures readily controlled, and mild or borderline mental retardation
Syndromes	
Down (trisomy 21)	Incidence 1 in 800 live births Abnormal rounding of occipital and frontal lobes and a small cerebellum; narrow superior temporal gyrus, propensity for Alzheimer neurofibrillary alterations, ultrastructure abnormalities of cerebral cortex
Edward (trisomy 18)	Incidence 1 in 6,500 live births Low birthweight, microstomia, micrognathia, low-set malformed ears, prominent occiput, rocker-bottom feet, flexion deformities of fingers, congenital heart disease, increased gyri, heterotopias of neurons
Cri-du-chat (5 p-)	Incidence 1 in 50,000 live births Round facies, prominent epicanthic folds, low-set ears, hypertelorism, characteristic cry No specific neuropathology
Cornelia de Lange	Prenatal and postnatal growth delay; synophrys; thin, downturning upper lip Proximally placed thumb
Rubinstein-Taybi	Beaked nose, downward slanting of palpebral fissures, epicanthic folds, short stature, broad thumbs and toes
Smith-Lemli-Opitz	Ptosis, scaphocephaly, inner epicanthic folds, anteverted nostrils Low birthweight, marked feeding problems
SECONDARY (NONGENETIC)	
Congenital Infections	
Cytomegalovirus	Small for dates, petechial rash, hepatosplenomegaly, chorioretinitis, deafness, mental retardation, seizures Central nervous system calcification and microgyria
Rubella	Growth retardation, purpura, thrombocytopenia, hepatosplenomegaly, congenital heart disease, chorioretinitis, cataracts, deafness Perivascular necrotic areas, polymicrogyria, heterotopias, subependymal cavitations
Toxoplasmosis	Purpura, hepatosplenomegaly, jaundice, convulsions, hydrocephalus, chorioretinitis, cerebral calcification
Drugs	
Fetal alcohol	Growth retardation, ptosis, absent philtrum and hypoplastic upper lip, congenital heart disease, feeding problems, neuroglial heterotopia, disorganization of neurons
Fetal hydantoin	Growth delay, hypoplasia of distal phalanges, inner epicanthic folds, broad nasal ridge, anteverted nostrils
Other Causes	
Radiation	Microcephaly and mental retardation most severe with exposure before 15th wk of gestation
Meningitis/encephalitis	Cerebral infarcts, cystic cavitation, diffuse loss of neurons
Malnutrition	Controversial cause of microcephaly
Metabolic	Maternal diabetes mellitus and maternal hyperphenylalaninemia
Hyperthermia	Significant fever during 1st 4-6 wk has been reported to cause microcephaly, seizures, and facial anomalies Pathologic studies show neuronal heterotopias Further studies show no abnormalities with maternal fever
Hypoxic–ischemic encephalopathy	Initially diffuse cerebral edema; late stages characterized by cerebral atrophy and abnormal signals on MRI

malformations such as lissencephaly, holoprosencephaly, polymicrogyria, cobblestone dysplasia, neuronal heterotopia, pontocerebellar hypoplasia; these should be sought on MRI. Secondary microcephaly results from a large number of noxious agents that can affect a fetus in utero or an infant during periods of rapid brain growth, particularly the 1st 2 yr of life.

Acquired microcephaly can be seen in conditions such as Rett, Seckel, and Angelman syndromes and in encephalopathy syndromes associated with severe seizure disorders.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

A thorough family history should be taken, seeking additional cases of microcephaly or disorders affecting the nervous system. It is important to measure a patient's head circumference at birth to diagnose microcephaly as early as possible. A very small head circumference implies a process that began early in embryonic or fetal development. An insult to the brain that occurs later in life, particularly beyond the age of 2 yr, is less likely to produce severe microcephaly. Serial head circumference measurements are more meaningful than a single determination, particularly when the abnormality is minimal. The head circumference of each parent and sibling should be recorded.

Laboratory investigation of a microcephalic child is determined by the history and physical examination. If the cause of the microcephaly is unknown, the mother's serum phenylalanine level should be determined. High phenylalanine serum levels in an asymptomatic mother can produce marked brain damage in an otherwise normal nonphenylketonuric infant. A karyotype and/or array comparative genomic hybridization study is obtained if a chromosomal syndrome is suspected or if the child has abnormal facies, short stature, and additional congenital anomalies. MRI is useful in identifying structural abnormalities of the brain such as lissencephaly, pachygyria, and polymicrogyria, and CT scanning is useful to detect intracerebral calcification. Additional studies include a fasting plasma and urine amino acid analysis; serum ammonia determination; *to*xoplasmosis, *r*ubella, *c*ytomegalovirus, and *h*erpes simplex (TORCH) titers as well as HIV testing of the mother and child; and a urine sample for the culture of cytomegalovirus. Single-gene mutations as a cause of both primary microcephaly and syndromic microcephaly are being increasingly identified.

TREATMENT

Once the cause of microcephaly has been established, the physician must provide accurate and supportive genetic and family counseling. Because many children with microcephaly are also intellectually challenged, the physician must assist with placement in an appropriate program that will provide for maximal development of the child (see Chapter 36).

591.11 Hydrocephalus

Stephen L. Kinsman and Michael V. Johnston

Hydrocephalus is not a specific disease; it represents a diverse group of conditions that result from impaired circulation and/or absorption of CSF or, in rare circumstances, from increased production of CSF by a choroid plexus papilloma (Table 591-4). Because megalencephaly is often discovered as part of an evaluation for hydrocephalus in children with macrocephaly, it is included in this section.

PHYSIOLOGY

The CSF is formed primarily in the ventricular system by the choroid plexus, which is situated in the lateral, third, and fourth ventricles. Although most CSF is produced in the lateral ventricles, approximately 25% originates from extrachoroidal sources, including the capillary endothelium within the brain parenchyma. There is active neurogenic control of CSF formation because adrenergic and cholinergic nerves innervate the choroid plexus. Stimulation of the adrenergic system diminishes CSF production, whereas excitation of the cholinergic nerves may double the normal CSF production rate. In a normal child, approximately 20 mL/hr of CSF is produced. The total volume of CSF approximates 50 mL in an infant and 150 mL in an adult. Most of the CSF is extraventricular. The choroid plexus forms CSF in several stages; through a series of intricate steps, a plasma ultrafiltrate is ultimately processed into a secretion, the CSF.

CSF flow results from the pressure gradient that exists between the ventricular system and venous channels. Intraventricular pressure may be as high as 180 mm H_2O in the normal state, whereas the pressure in the superior sagittal sinus is in the range of 90 mm H_2O. Normally, CSF flows from the lateral ventricles through the foramina of Monro into the 3rd ventricle. It then traverses the narrow aqueduct of Sylvius, which is approximately 3 mm long and 2 mm in diameter in a child, to enter the fourth ventricle. The CSF exits the fourth ventricle through the paired lateral foramina of Luschka and the midline foramen of Magendie into the cisterns at the base of the brain. Hydrocephalus resulting from obstruction within the ventricular system is called obstructive or noncommunicating hydrocephalus. The CSF then circulates from the basal cisterns posteriorly through the cistern system and over the convexities of the cerebral hemispheres. CSF is absorbed primarily by the arachnoid villi through tight junctions of their endothelium by the pressure forces that were noted earlier. CSF is absorbed to a much lesser extent by the lymphatic channels directed to the paranasal sinuses, along nerve root sleeves, and by the choroid plexus itself. Hydrocephalus resulting from obliteration of the subarachnoid cisterns or malfunction of the arachnoid villi is called nonobstructive or communicating hydrocephalus.

PATHOPHYSIOLOGY AND ETIOLOGY

Obstructive or noncommunicating hydrocephalus develops most commonly in children because of an abnormality of the aqueduct of Sylvius or a lesion in the fourth ventricle. Aqueductal stenosis results from an abnormally narrow aqueduct of Sylvius that is often associated with

branching or forking. In a small percentage of cases, aqueductal stenosis is inherited as a sex-linked recessive trait. These patients occasionally have minor neural tube closure defects, including spina bifida occulta. Rarely, aqueductal stenosis is associated with neurofibromatosis. Aqueductal gliosis can also give rise to hydrocephalus. As a result of neonatal meningitis or a subarachnoid hemorrhage in a premature infant, the ependymal lining of the aqueduct is interrupted and a brisk glial response results in complete obstruction. Intrauterine viral infections can also produce aqueductal stenosis followed by hydrocephalus, and mumps meningoencephalitis has been reported as a cause in a child. A vein of Galen malformation can expand to become large and, because of its midline position, obstruct the flow of CSF. Lesions or malformations of the posterior fossa are prominent causes of hydrocephalus, including posterior fossa brain tumors, Chiari malformation, and the Dandy-Walker syndrome.

Nonobstructive or communicating hydrocephalus most commonly follows a subarachnoid hemorrhage, which is usually a result of intraventricular hemorrhage in a premature infant. Blood in the subarachnoid spaces can cause obliteration of the cisterns or arachnoid villi and obstruction of CSF flow. Pneumococcal and tuberculous meningitis have a propensity to produce a thick, tenacious exudate that obstructs the basal cisterns, and intrauterine infections can also destroy the CSF pathways. Leukemic infiltrates can seed the subarachnoid space and produce communicating hydrocephalus.

CLINICAL MANIFESTATIONS

The clinical presentation of hydrocephalus is variable and depends on many factors, including the age at onset, the nature of the lesion causing obstruction, and the duration and rate of increase of the intracranial pressure (ICP). In an infant, an accelerated rate of enlargement of the head is the most prominent sign. In addition, the anterior fontanel is wide open and bulging, and the scalp veins are dilated. The forehead is broad, and the eyes might deviate downward because of impingement of the dilated suprapineal recess on the brainstem tectum, producing the setting-sun eye sign. Long-tract signs, including brisk tendon reflexes, spasticity, clonus (particularly in the lower extremities), and Babinski sign, are common owing to stretching and disruption of the corticospinal fibers originating from the leg region of the motor cortex. In an older child, the cranial sutures are less accommodating so that the signs of hydrocephalus may be subtler. Irritability, lethargy, poor appetite, and vomiting are common to both age groups, and headache is a prominent symptom in older patients. A gradual change in personality and deterioration in academic productivity suggest a slowly progressive form of hydrocephalus. With regard to other clinical signs, serial measurements of the head circumference often indicate an increased velocity of growth. Percussion of the skull might produce a cracked pot sound or Macewen sign, indicating separation of the sutures. A foreshortened occiput suggests Chiari malformation, and a prominent occiput suggests the Dandy-Walker malformation. Papilledema, abducens nerve palsies, and pyramidal tract signs, which are most evident in the lower extremities, are apparent in many cases.

Chiari malformation consists of 2 major subgroups. Type I typically produces symptoms during adolescence or adult life and is usually not associated with hydrocephalus. Patients complain of recurrent headache, neck pain, urinary frequency, and progressive lower-extremity spasticity. The deformity consists of displacement of the cerebellar tonsils into the cervical canal (Fig. 591-12). Syrinx of the spinal cord, especially the cervical region should be looked for on MRI imaging. Although the pathogenesis is unknown, a prevailing theory suggests that obstruction of the caudal portion of the fourth ventricle during fetal development is responsible. Other theories include tethering of the cord or additional anomalies (syrinx).

The type II Chiari malformation is characterized by progressive hydrocephalus with a myelomeningocele. This lesion represents an anomaly of the hindbrain, probably owing to a failure of pontine flexure development during embryogenesis, and results in elongation of the fourth ventricle and kinking of the brainstem, with displacement of the inferior vermis, pons, and medulla into the cervical canal

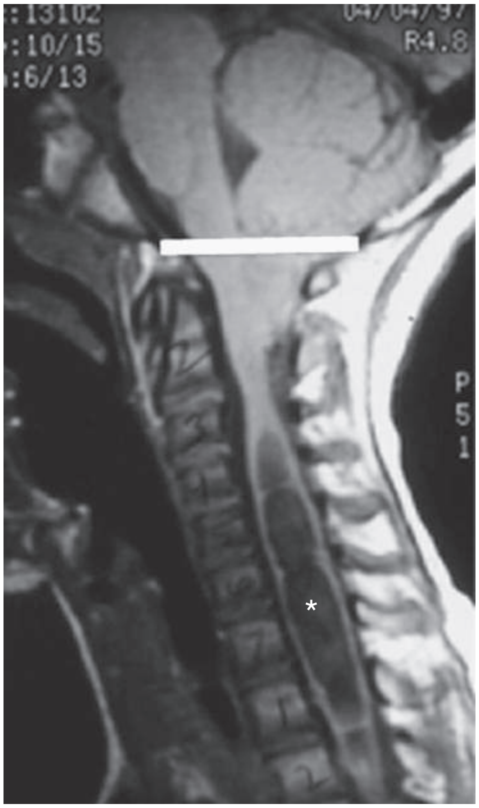

Figure 591-12 Sagittal MR scan of a patient with Chiari malformation type I. Cerebellar tonsils are displaced through the foramen magnum *(white bar)* to the lower aspect of C2 with clear crowding at the foramen. A syrinx *(white asterisk)* is visible extending from C3 to T2. *(From Yassari R, Frim D: Evaluation and management of the Chiari malformation type 1 for the primary care pediatrician,* Pediatr Clin North Am *51:477–490, 2004.)*

(Fig. 591-13). Approximately 10% of type II malformations produce symptoms during infancy, consisting of stridor, weak cry, and apnea, which may be relieved by shunting or by decompression of the posterior fossa. A more indolent form consists of abnormalities of gait, spasticity, and increasing incoordination (including the arms and hands) during childhood.

Plain skull radiographs show a small posterior fossa and a widened cervical canal. CT scanning with contrast and MRI display the cerebellar tonsils protruding downward into the cervical canal and the hindbrain abnormalities. The anomaly is treated by surgical decompression, but asymptomatic or mildly symptomatic patients may be managed conservatively.

The Dandy-Walker malformation consists of a cystic expansion of the fourth ventricle in the posterior fossa and midline cerebellar hypoplasia, which results from a developmental failure of the roof of the fourth ventricle during embryogenesis (Fig. 591-14). Approximately 90% of patients have hydrocephalus, and a significant number of children have associated anomalies, including agenesis of the posterior cerebellar vermis and corpus callosum. Infants present with a rapid increase in head size and a prominent occiput. Transillumination of the skull may be positive. Most children have evidence of long-tract signs, cerebellar ataxia, and delayed motor and cognitive milestones, probably due to the associated structural anomalies. The Dandy-Walker malformation is managed by shunting the cystic cavity (and on occasion the ventricles as well) in the presence of hydrocephalus.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Investigation of a child with hydrocephalus begins with the history. Familial cases suggest X-linked or autosomal hydrocephalus secondary to aqueductal stenosis. A past history of prematurity with intracranial

hemorrhage, meningitis, or mumps encephalitis is important to ascertain. Multiple café-au-lait spots and other clinical features of neurofibromatosis point to aqueductal stenosis as the cause of hydrocephalus.

Examination includes careful inspection, palpation, and auscultation of the skull and spine. The occipitofrontal head circumference is recorded and compared with previous measurements. The size and configuration of the anterior fontanel are noted, and the back is inspected for abnormal midline skin lesions, including tufts of hair, lipoma, or angioma that might suggest spinal dysraphism. The presence of a prominent forehead or abnormalities in the shape of the occiput can suggest the pathogenesis of the hydrocephalus. A cranial bruit is audible in association with many cases of vein of Galen arteriovenous malformation. Transillumination of the skull is positive with massive dilation of the ventricular system or in the Dandy-Walker syndrome. Inspection of the eyegrounds is mandatory because the finding of chorioretinitis suggests an intrauterine infection, such as toxoplasmosis, as a cause of the hydrocephalus. Papilledema is observed in older children but is rarely present in infants because the cranial sutures separate as a result of the increased pressure.

Plain skull films typically show separation of the sutures, erosion of the posterior clinoids in an older child, and an increase in convolutional markings (beaten-silver appearance) on the inside of the skull with long-standing increased ICP. The CT scan and/or MRI along with ultrasonography in an infant are the most important studies to identify the specific cause and severity of hydrocephalus.

The head might appear enlarged (and can be confused with hydrocephalus) secondary to a thickened cranium resulting from chronic anemia, rickets, osteogenesis imperfecta, and epiphyseal dysplasia. Chronic subdural collections can produce bilateral parietal bone prominence. MRI has revealed the common occurrence of benign external hydrocephalus, a growth-limited condition where intervention is rarely required. Various metabolic and degenerative disorders of the CNS produce megalencephaly as a result of abnormal storage of substances within the brain parenchyma. These disorders include lysosomal diseases (Tay-Sachs disease, gangliosidosis, and the mucopolysaccharidoses), the aminoacidurias (maple syrup urine disease), and the leukodystrophies (metachromatic leukodystrophy, Alexander disease, Canavan disease). In addition, cerebral gigantism (Sotos syndrome), other overgrowth syndromes and neurofibromatosis are characterized by increased brain mass. Familial megalencephaly is inherited as an autosomal dominant trait and is characterized by delayed motor milestones and hypotonia but normal or near-normal intelligence. Measurement of parents' head circumferences is necessary to establish the diagnosis.

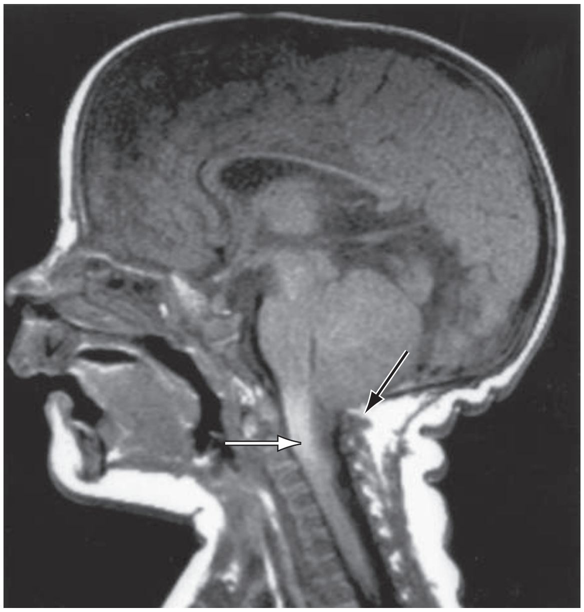

Figure 591-13 A midsagittal T1-weighted MRI of a patient with type II Chiari malformation. The cerebellar tonsils *(white arrow)* have descended below the foramen magnum *(black arrow)*. Note the small, slitlike fourth ventricle, which has been pulled into a vertical position.

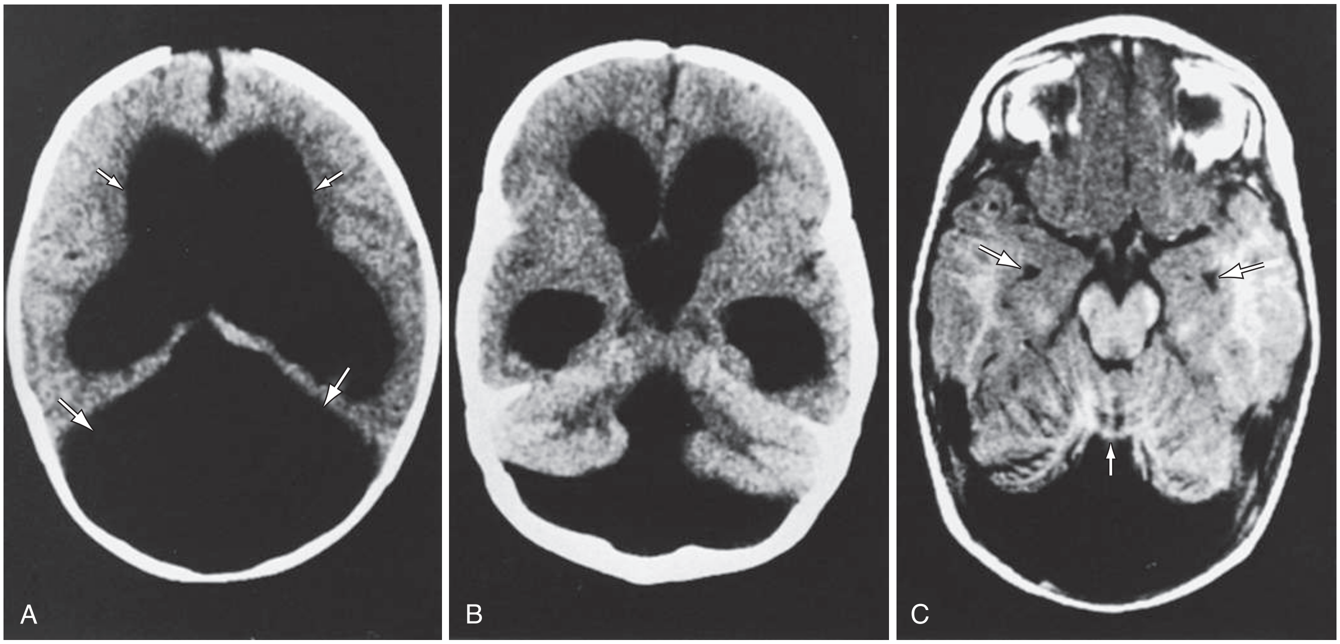

Figure 591-14 Dandy-Walker cyst. **A,** Axial CT scan (preoperative) showing large posterior fossa cyst (Dandy-Walker cyst; *large arrows*) and dilated lateral ventricles *(small arrows)*, a complication secondary to cerebrospinal fluid (CSF) pathway obstruction at the fourth ventricular outlet. **B,** Same patient, with a lower axial CT scan showing splaying of the cerebellar hemispheres by the dilated fourth ventricle (Dandy-Walker cyst). The dilated ventricles proximal to the fourth ventricle again show CSF obstruction caused by the Dandy-Walker cyst. **C,** MRI of the same patient showing decreased size of the Dandy-Walker cyst and temporal horns *(arrows)* after shunting. The incomplete vermis *(small arrow)* now becomes recognizable.

MEGALENCEPHALY

Megalencephaly is an anatomic disorder of brain growth defined as a brain weight : volume ratio >98th percentile for age (or ≥2 SD above the mean) that is usually accompanied by macrocephaly (an occipitofrontal circumference >98th percentile). Various storage and degenerative diseases are associated with megalencephaly, but anatomic and genetic causes exist as well. The most common cause of anatomic megalencephaly is benign familial megalencephaly. This condition is easily diagnosed by careful family history and measurement of the parents' head circumferences (occipitofrontal circumferences). On the other hand, macrocephaly is a known feature of more than 100 syndromes.

Anatomic megalencephaly is usually apparent at birth, and head growth continues to run parallel to the upper percentiles. Sometimes, in some syndromes, increased occipitofrontal circumference is the presenting sign. Neuroimaging is critical in identifying the various structural and gyral abnormalities seen in syndromic macrocephaly and determining whether anatomic megalencephaly exists.

Common megalencephaly-associated macrocephaly syndromes include syndromes with prenatal and/or postnatal somatic overgrowth such as Sotos, Simpson-Golabi-Behmel, fragile X, Weaver, macrocephaly-cutis marmorata telangiectatica congenita, and Bannayan-Ruvalcaba-Riley syndromes, and syndromes without somatic overgrowth such as FG, Greig cephalopolysyndactyly, acrocallosal, and Gorlin.

Sotos syndrome (cerebral gigantism) is the most common megalencephalic syndrome, with 50% of patients having prenatal macrocephaly and 100% of patients having macrocephaly by age 1 yr. Early postnatal overgrowth normalizes by adulthood. Facial features include high forehead with frontal bossing, sparse hair in the frontoparietal region, downslanting palpebral fissures, apparent hypertelorism, long narrow face, prominent mandible, and malar flushing. Hypotonia, poor coordination, and speech delay are common. Most children show cognitive impairment, ranging from mild to severe.

HYDRANENCEPHALY

Hydranencephaly may be confused with hydrocephalus. The cerebral hemispheres are absent or represented by membranous sacs with remnants of frontal, temporal, or occipital cortex dispersed over the membrane. The midbrain and brainstem are relatively intact (Fig. 591-15).

Figure 591-15 Hydranencephaly. MRI scan showing the brainstem and spinal cord with remnants of the cerebellum and the cerebral cortex. The remainder of the cranium is filled with cerebrospinal fluid.

The cause of hydranencephaly is unknown, but bilateral occlusion of the internal carotid arteries during early fetal development would explain most of the pathologic abnormalities. Affected infants can have a normal or enlarged head circumference at birth that grows at an excessive rate postnatally. Transillumination shows an absence of the cerebral hemispheres. The child is irritable, feeds poorly, develops seizures and spastic quadriparesis, and has little or no cognitive development. A ventriculoperitoneal shunt prevents massive enlargement of the cranium.

TREATMENT

Therapy for hydrocephalus depends on the cause. Medical management, including the use of acetazolamide and furosemide, can provide temporary relief by reducing the rate of CSF production, but long-term results have been disappointing. Most cases of hydrocephalus require extracranial shunts, particularly a ventriculoperitoneal shunt. Endoscopic third ventriculostomy has evolved as a viable approach and criteria have been developed for its use, but the procedure might need to be repeated to be effective. Ventricular shunting may be avoided with this approach. The major complications of shunting are occlusion (characterized by headache, papilledema, emesis, mental status changes) and bacterial infection (fever, headache, meningismus), usually caused by *Staphylococcus epidermidis*. With meticulous preparation, the shunt infection rate can be reduced to <5%. The results of intrauterine surgical management of fetal hydrocephalus have been poor (possibly because of the high rate of associated cerebral malformations in addition to the hydrocephalus) except for some promise in cases of hydrocephalus associated with fetal meningomyelocele.

PROGNOSIS

Prognosis depends on the cause of the dilated ventricles and not on the size of the cortical mantle at the time of operative intervention, except in cases in which the cortical mantle has been severely compressed and stretched. Hydrocephalic children are at increased risk for various developmental disabilities. The mean intelligence quotient is reduced compared with the general population, particularly for performance tasks as compared with verbal abilities. Many children have abnormalities in memory function. Vision problems are common, including strabismus, visuospatial abnormalities, visual field defects, and optic atrophy with decreased acuity secondary to increased ICP. The visual evoked potential latencies are delayed and take some time to recover after correction of the hydrocephalus. Although most hydrocephalic children are pleasant and mild mannered, some children show aggressive and delinquent behavior. Accelerated pubertal development in patients with shunted hydrocephalus or myelomeningocele is relatively common, possibly because of increased gonadotropin secretion in response to increased ICP. It is imperative that hydrocephalic children receive long-term follow-up in a multidisciplinary setting.

591.12 Craniosynostosis

Stephen L. Kinsman and Michael V. Johnston

Craniosynostosis is defined as premature closure of the cranial sutures and is classified as primary or secondary. It is associated with varying types of abnormal skull shape. Primary craniosynostosis refers to closure of 1 or more sutures owing to abnormalities of skull development, whereas secondary craniosynostosis results from failure of brain growth and expansion and is not discussed here. The incidence of primary craniosynostosis approximates 1 in 2,000 live births. The cause is unknown in the majority of children; however, genetic syndromes account for 10-20% of cases. Deformational forces appear important in occipital and frontal plagiocephaly in many cases. Early detection of posterior skull shape is critical and allows successful intervention to be offered in the form of physical therapy for torticollis and other positional asymmetries that lead to plagiocephaly.

DEVELOPMENT AND ETIOLOGY

The bones of the cranium are well developed by the 5th mo of gestation (frontal, parietal, temporal, and occipital) and are separated by sutures and fontanels. The brain grows rapidly in the 1st several yr of life and is normally not impeded because of equivalent growth along the suture lines. The cause of craniosynostosis is unknown, but the prevailing hypothesis suggests that abnormal development of the base of the skull creates exaggerated forces on the dura that act to disrupt normal cranial suture development. Genetic factors have been identified for some isolated and for many syndromic causes of craniosynostosis (Table 591-5).

Table 591-5 Commonly Used Clinical Genetic Classifications of Craniosynostoses

DISORDER	CAUSE
ISOLATED CRANIOSYNOSTOSIS	
Morphologically described	Unknown, uterine constraint, or *FGFR3* mutation
SYNDROMIC CRANIOSYNOSTOSIS	
Antler-Bixler syndrome	Unknown
Apert syndrome	Usually 1 of 2 mutations in *FGFR2*
Beare-Stevenson syndrome	Mutation in *GFGR2* or *FGFR3*
Baller-Gerold syndrome	Mutation in *TWIST* heterogenous
Carpenter syndrome	Unknown
Craniofrontonasal dysplasia	Unknown gene at *Xp22*
Crouzon syndrome	Numerous different mutations at *FGFR2*
Crouzonomesodermoskeletal syndrome	Mutation in *FGFR3*
Jackson-Weiss syndrome	Mutation in *FGFR2*
Muenke syndrome	Mutation in *FGFR3*
Pfeiffer syndrome	Mutation in *FGFR1* or numerous mutation in *FGFR2*
Saethre-Chotzen syndrome	Mutation in *TWIST*
Shprintzen-Goldberg syndrome	Mutation in *FBEN1*

From Ridgway EB, Weiner HL: Skull deformities, Pediatr Clin North Am *51:359–387, 2004.*

CLINICAL MANIFESTATIONS AND TREATMENT

Most cases of craniosynostosis are evident at birth and are characterized by a skull deformity that is a direct result of premature suture fusion. Palpation of the suture reveals a prominent bony ridge, and fusion of the suture may be confirmed by plain skull roentgenograms, CT scan, or bone scan in ambiguous cases (Table 591-6).

Premature closure of the sagittal suture produces a long and narrow skull, or **scaphocephaly,** the most common form of craniosynostosis. Scaphocephaly is associated with a prominent occiput, a broad forehead, and a small or absent anterior fontanel. The condition is sporadic, is more common in males, and often causes difficulties during labor because of cephalopelvic disproportion. Scaphocephaly does not produce increased ICP or hydrocephalus, and results of neurologic examination of affected patients are normal.

Frontal plagiocephaly is the next most common form of craniosynostosis and is characterized by unilateral flattening of the forehead, elevation of the ipsilateral orbit and eyebrow, and a prominent ear on the corresponding side. The condition is more common in females and is the result of premature fusion of a coronal and sphenofrontal suture. Surgical intervention produces a cosmetically pleasing result. When imaging does not reveal a closed suture, positional factors are of primary importance.

Occipital plagiocephaly is most often a result of positioning during infancy and is more common in an immobile child or a child with a disability, but fusion or sclerosis of the lambdoid suture can cause unilateral occipital flattening and bulging of the ipsilateral frontal bone. **Trigonocephaly** is a rare form of craniosynostosis caused by premature fusion of the metopic suture. These children have a keel-shaped forehead and hypotelorism and are at risk for associated developmental abnormalities of the forebrain. Milder forms of metopic ridging are more common. **Turricephaly** refers to a cone-shaped head from premature fusion of the coronal, and often sphenofrontal and frontoethmoidal, sutures. The **kleeblattschädel deformity** is a peculiarly shaped skull that resembles a cloverleaf. Affected children have very prominent temporal bones, and the remainder of the cranium is constricted. Hydrocephalus is a common complication.

Premature fusion of only 1 suture rarely causes a neurologic deficit. In this situation, the sole indication for surgery is to enhance the child's cosmetic appearance, and the prognosis depends on the suture involved

Table 591-6 Epidemiology and Clinical Characteristics of the Common Craniosynostoses

TYPE	EPIDEMIOLOGY	SKULL DEFORMITY	CLINICAL PRESENTATION
Sagittal	Most common CSO affecting a single suture, 80% male	Dolicocephaly or scaphocephaly (boat-shaped)	Frontal bossing, prominent occiput, palpable keel ridge. OFC normal and reduced biparietal diameter
Coronal	18% of CSO, more common in girls Associated with Apert syndrome (with syndactyly) and Crouzon disease, which includes abnormal sphenoid, orbital, and facial bones (hypoplasia of the midface)	Unilateral: plagiocephaly Bilateral: brachycephaly, acrocephaly	Unilateral: flattened forehead on affected side, flat checks, nose deviation on normal side; higher supraorbital margin leading to harlequin sign on radiograph and outward rotation of orbit can result in amblyopia Bilateral: broad, flattened forehead. In Apert syndrome accompanied by syndactyly and in Crouzon disease by hypoplasia of the midface and progressive proptosis
Lambdoid	10-20% of CSO, M:F ratio 4:1	Lambdoid/occipital plagiocephaly; right side affected in 70% of cases	Unilateral: flattening of occiput, indentation along synostotic suture, bulging of ipsilateral forehead leading to rhomboid skull, ipsilateral ear is anterior and inferior Bilateral: brachycephaly with bilateral anteriorly and inferiorly displaced ears
Metopic	Association with 19p chromosome abnormality	Trigonocephaly	Pointed forehead and midline ridge, hypotelorism
Multiple		Oxycephaly	Tower skull with undeveloped sinuses and shallow orbits, and elevated intercranial pressure

CSO, craniosynostosis; OFC, occipital-frontal circumference.

From Ridgway EB, Weiner HL: Skull deformities, Pediatr Clin North Am *51:359–387, 2004.*

and on the degree of disfigurement. Neurologic complications, including hydrocephalus and increased ICP, are more likely to occur when 2 or more sutures are prematurely fused, in which case operative intervention is essential. The role of early repositioning efforts and therapy for torticollis and the use of cranial molding devices are beyond the scope of this review.

The most prevalent genetic disorders associated with craniosynostosis include Crouzon, Apert, Carpenter, Chotzen, and Pfeiffer syndromes. Crouzon syndrome is characterized by premature craniosynostosis and is inherited as an autosomal dominant trait. The shape of the head depends on the timing and order of suture fusion but most often is a compressed back-to-front diameter or brachycephaly resulting from bilateral closure of the coronal sutures. The orbits are underdeveloped, and ocular proptosis is prominent. Hypoplasia of the maxilla and orbital hypertelorism are typical facial features.

Apert syndrome has many features in common with Crouzon syndrome. Apert syndrome is usually a sporadic condition, although autosomal dominant inheritance can occur. It is associated with premature fusion of multiple sutures, including the coronal, sagittal, squamosal, and lambdoid sutures. The facies tend to be asymmetric, and the eyes are less proptotic than in Crouzon syndrome. Apert syndrome is characterized by syndactyly of the 2nd, 3rd, and 4th fingers, which may be joined to the thumb and the 5th finger. Similar abnormalities often occur in the feet. All patients have progressive calcification and fusion of the bones of the hands, feet, and cervical spine.

Carpenter syndrome is inherited as an autosomal recessive condition, and the many fusions of sutures tend to produce the kleeblattschädel skull deformity. Soft tissue syndactyly of the hands and feet is always present, and intellectual disability is common. Additional but less common abnormalities include congenital heart disease, corneal opacities, coxa valga, and genu valgum.

Chotzen syndrome is characterized by asymmetric craniosynostosis and plagiocephaly. The condition is the most prevalent of the genetic syndromes and is inherited as an autosomal dominant trait. It is associated with facial asymmetry, ptosis of the eyelids, shortened fingers, and soft tissue syndactyly of the 2nd and 3rd fingers.

Pfeiffer syndrome is most often associated with turricephaly. The eyes are prominent and widely spaced, and the thumbs and great toes are short and broad. Partial soft-tissue syndactyly may be evident. Most cases appear to be sporadic, but autosomal dominant inheritance has been reported.

Mutations of the fibroblast growth factor receptor (FGFR) gene family have been shown to be associated with phenotypically specific types of craniosynostosis. Mutations of the *FGFR1* gene located on chromosome 8 result in Pfeiffer syndrome; a similar mutation of the *FGFR2* gene causes Apert syndrome. Identical mutations of the *FGFR2* gene can result in both Pfeiffer and Crouzon phenotypes.

Each of the genetic syndromes poses a risk of additional anomalies, including hydrocephalus, increased ICP, papilledema, optic atrophy resulting from abnormalities of the optic foramina, respiratory problems secondary to a deviated nasal septum or choanal atresia, and disorders of speech and deafness. Craniectomy is mandatory for management of increased ICP, and a multidisciplinary craniofacial team is essential for the long-term follow-up of affected children. Craniosynostosis may be surgically corrected with good outcomes and relatively low morbidity and mortality, especially for nonsyndromic infants.

Chapter 592 Deformational Plagiocephaly

René P. Myers, Aubrey N. Duncan, and John A. Girotto

Deformational plagiocephaly (DP), also known as positional plagiocephaly, is the development of cranial flattening and asymmetry in the infant *as a result of extrinsic molding forces placed on the skull, such as consistently sleeping on the same area of the head*. Since the suggestion to place sleeping infants on their backs to sleep for the prevention of the **sudden infant death syndrome**, the incidence of DP has risen dramatically, and this has caused concern for parents and clinicians in the primary care setting.

EPIDEMIOLOGY AND ETIOLOGY

Incidence

The incidence is frequent at 6 wk of age (16%), greatest at 4 mo of age (up to 20%), and then decreases over the next 3 yr (7% at 12 mo and 3.3% at 24 mo). It generally resolves completely by 2-3 yr of age. The American Academy of Pediatrics started a campaign in the 1990s that resulted in the recommendation to place infants on their backs or sides while sleeping, which resulted in a 40% decrease in sudden infant death syndrome cases. Within 4 yr, craniofacial centers and primary care offices reported a 600% increase in referrals for plagiocephaly, which was previously reported to be approximately 1 in 300 infants. This may be a result of increasing awareness or early referral, as point prevalence has not changed in the past 40 yr.

Infants cannot reposition their heads in the 1st few wk of life and are not able to hold their own heads up until about 4 mo of age. It is for this reason that DP is most severe around 4 mo of age. It is also during this time that an infant's head circumference is rapidly increasing: about 2 cm/month in the 1st 3 mo, 1 cm/month from 4-6 mo of age, and 0.5 cm/month after 6 mo of age. Around 6 mo of age, an infant has developed head control, and this ability to actively reposition their own head allows for the gradual improvement of the cranial shape because of pressure offloading and continued brain growth.

Risk Factors

Congenital torticollis, positional preference when sleeping, and lower levels of activity are especially prominent in patients with DP. Table 592-1 delineates other risk factors. Many of these risk factors cannot be prevented, but sleeping supine with the head always turned to the same side has been found to predict DP independent of the other factors, and this *can* be prevented. There may be an association between developmental delay and DP. Although not causal, studies have found significant differences in gross motor development such as sitting up, crawling, and rolling back to side, between babies with and without DP.

Table 592-1	Factors That Increase Risk for Deformational Plagiocephaly
Male	
Firstborn child	
Limited passive neck rotation at birth (e.g., congenital torticollis)	
Developmental delay	
Sleep position is supine at birth and at 6 weeks	
Bottle feeding only	
Tummy time <3 times/day	
Lower activity level, slower milestone achievement	
Sleeping with head to same side, positional preference	

Causes

Prenatal causes of DP include uterine compression and intrauterine constraint, such as occurs with oligohydramnios or multifetus gestation. Postnatal causes of DP include infant sleeping position and congenital muscular torticollis.

Muscular torticollis is a condition that is present in as many as 1 in 6 newborns and causes continuous tightening of muscles in the neck preventing passive rotation. It is thought that this condition typically precedes the development of cranial deformity. However, head position preference may result from cervical asymmetry that leads to torticollis and later flattening of a side of the skull from acquired positional preference (see Chapter 680.1).

Sleeping position plays a major role in the incidence of DP. When an infant continuously sleeps with the same part of the skull resting on a flat surface, a continuous force is placed in this area. During this time of rapid skull development, the growth is inhibited at the area where it rests on a hard surface, causing a "flat spot." Because of this inhibition, growth is increased in opposite directions causing a deformation that can be distinguished from other types of plagiocephaly.

EXAMINATION AND DIFFERENTIATING BETWEEN DEFORMATIONAL PLAGIOCEPHALY AND CRANIOSYNOSTOSIS

Abnormal head shape in an infant is distressing for parents. DP is a clinical diagnosis. Management also requires accurate counseling about its cause and treatment. It is especially important to be able to rule out **craniosynostosis** as a primary cause for cranial asymmetry in infants, as management of this condition is very different from that of DP and requires immediate referral to a craniofacial surgeon for evaluation (see Chapter 591.12). Craniosynostosis occurs in approximately 1 in 2,000 live births and results in plagiocephaly as a consequence of the early closure of skull sutures. Craniosynostosis must be distinguished from DP because the management is different. Lambdoidal craniosynostosis, although extremely rare (1 in 300,000 live births), presents with features most similar to those of DP. It can be distinguished from DP by a variety of historical and physical findings. Bilateral coronal synostosis also presents very similarly to posterior DP.

History and Physical Exam

Tables 592-2 and 592-3 outline the key components of history and physical examination.

Observation of the cranial shape as well as ear displacement are the first steps. It is critical to observe the child anteriorly, laterally, and from a vertex view. When cranial shape is viewed from above, DP typically looks like a **parallelogram**, and the ear on the same side of the flat or bald spot is **displaced anteriorly**. In lambdoidal craniosynostosis, the head has a trapezoid shape and the ear on the same side as the flat spot is posteriorly displaced (Fig. 592-1).

Palpation will help to differentiate these 2 conditions. Craniosynostosis presents with palpable ridges along the suture, whereas DP does not. Additionally, patients with craniosynostosis will not have mobile calvarial bones. This can be tested by applying gentle pressure on 2

Table 592-2 Important Historical and Physical Factors in the Evaluation of a Patient with Plagiocephaly

	DEFORMATIONAL	SYNOSTOTIC
Birth history	• Intrauterine compression • Firstborn child	• Typically no complications
Head shape at birth	• Typically normal	• Can be irregular
Age first noticed shape irregularity	• Usually in 1st few mo of life	• Can be at birth
How patient prefers to sleep	• Same side, same position • Same even during naps	• Variable
Bald spot	• Yes	• No
Motor development for age	• If age atypical for deformational plagiocephaly, typically slow motor development for age • Torticollis present • History of limited activity or mobility	• Varies depending on presence of concomitant syndrome
Tummy time	• Decreased	• Suggested time
Signs/symptoms of increasing intracranial pressure	• No	• Possible

Table 592-3 Key Differences Between Synostotic (Craniosynostosis) and Deformational Plagiocephaly

	DEFORMATIONAL PLAGIOCEPHALY	CRANIOSYNOSTOSIS
Causes	External forces applied to the skull • Prenatal: uterine compression, intrauterine constrained • Postnatal: congenital torticollis, sleeping position	Premature fusion of 1 or more cranial sutures
Common types	• Lateral • Posterior	• Bilateral coronal • Sagittal • Metopic
Common distinguishing features	• Normal round head shape at birth • Parallelogram shape to head • Ipsilateral ear anteriorly displaced • No palpable bony ridges	• Can have abnormal head shape at birth • Trapezoid shape to head • Ipsilateral ear posteriorly displaced • Palpable bony ridges
Management	• Repositioning • Physical therapy • Helmet in some cases	• Surgery • Helmet in some cases

Adapted from Nield LS, Brunner MD, Kamat D: The infant with a misshapen head. Clin Pediatr (Phila) *46:292–298, 2007, Tables 1 and 2.*

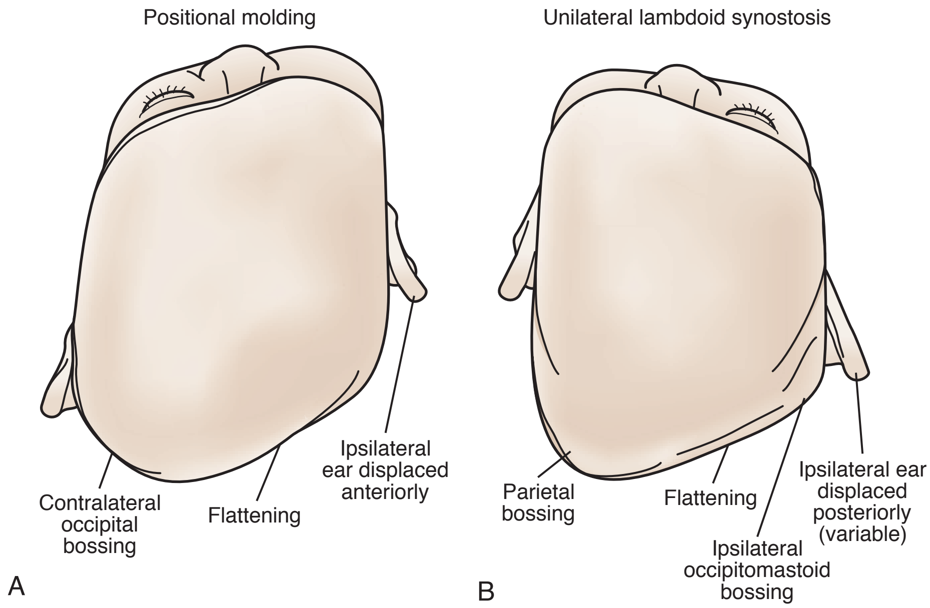

Figure 592-1 **Differentiating physical findings between deformational plagiocephaly and craniosynostosis.** Vertex views. **A,** Right-sided deformational plagiocephaly exhibiting a parallelogram head shape. **B,** Right-sided lambdoid craniosynostosis exhibiting a trapezoid-like head shape. *(From Lin AY, Losee JE: Pediatric plastic surgery. In Zitelli BJ, McIntire SC, Norwalk AJ, editors:* Zitelli and Davis' atlas of pediatric physical diagnosis, *ed 6, Philadelphia, 2012, Elsevier,* Fig. 22-5.*)*

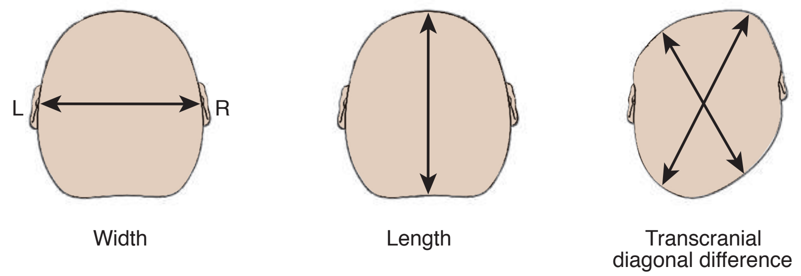

Figure 592-2 **Cranial measurements.** *(Modified from Looman WS, Flannery AB: Evidence-based care of the child with deformational plagiocephaly, part I: assessment and diagnosis.* J Pediatr Health Care *26:242–250, 2012, Table 1.)*

adjacent skull bones separated by a suspected synostotic suture. If the plates do not move relative to each other, then the suspicion for craniosynostosis is raised.

Verifying neck muscle tone and range of motion is a key part of the exam because it helps in evaluating motor development and in diagnosing congenital torticollis. Resistance to passive motion raises the concern for torticollis. Decreased tone should prompt further evaluation of motor development. Infants do not gain the muscle control to turn or lift their heads until approximately 4 mo of age, and delays in motor development could increase the infant's risk of DP at later ages than those at which it usually occurs. Decreased range of motion can also be seen in cervical spine abnormalities, although this is rare. Early recognition of these conditions is critical in treatment, management, and outcome.

Accurate and consistent measurements will help to distinguish etiologies and manage infants presenting with an abnormal-shape skull. Along with the usual head circumference measurements, the clinician should also measure cranial width, length, and transcranial diameter (as shown in Figure 592-2), which is best performed with calipers. These measurements allow the clinician to diagnose, determine severity, and monitor the plagiocephaly.

- *Cranial length:* Distance from the most prominent point between the eyebrows to the most prominent point of the occiput
- *Width:* Maximum transverse diameter, horizontal
- *Cephalic index* (cranial index): Ratio of the cranial width to the cranial length
- *Occipital-frontal transcranial diameter*: Find the points on either side of the head where the deformation is the worst (2 on the right, 2 on the left), then measure the **diagonal distances** between these points
- *Transdiagonal difference* (transcranial diagonal difference): The difference between 2 transcranial diameters
- *Cranial vault asymmetry:* Ratio of oblique measurements. This is difficult to implement because different physicians and authors propose varying points to use for these measurements

One technology for the evaluation of the severity and improvement over time of DP is the 3-dimensional photographic system. Advantages of this system include an easy and comfortable ability to image in an unbiased manner. Similarly, the use of laser scanners for the prefabrication scans for helmets is frequently employed by orthotists.

After observations and measurements the clinician can determine the type and severity of the DP (Table 592-4 and Fig. 592-3). For *lateral DP*, bossing of the occiput occurs opposite the flattened deformity and the ear on the same side as the flat area can be anteriorly displaced. This type of DP is typically associated with infants who have torticollis or a head position preference to 1 side. Transdiagonal diameter is typically abnormal in this type of plagiocephaly, and this measurement is the gold standard for determining severity.

In *posterior DP*, the occiput is uniformly flattened, temporal bossing can occur, and the ears are normal. It is usually associated with large head size and a history of limited activity or mobility. Cephalic index is increased with posterior DP.

Time and accurate exam records can help in management. If deformation is worsening when DP typically begins to demonstrate improving head shape, craniosynostosis should be suspected.

TREATMENT

Prevention

Sleep position should be monitored and varied. Alternating the infant's head to face the head and foot of the crib on alternate nights will allow the infant to sleep facing into the room without always lying on the same side of the head. Consistently alternating sleeping position early on allows the infant to have equal time on both sides of the occiput, and this will become a pattern the infant is used to. Infants who have

Table 592-4 Diagnostic Guide for Determining Type and Severity of Lateral and Posterior Deformational Plagiocephaly

TYPE

CLINICAL FINDINGS	LATERAL DEFORMATIONAL PLAGIOCEPHALY	POSTERIOR DEFORMATIONAL PLAGIOCEPHALY (BRACHYCEPHALY)
Occiput (vertex view)	Ipsilateral occipital flattening; contralateral occipital bossing	Uniform occipital flattening
Ear position (vertex view)	Ipsilateral ear may be anteriorly displaced	Normal
Face, forehead (anterior, lateral, and vertex views)	May be normal; more-severe cases may present with the following: mandibular asymmetry, ipsilateral frontal bossing, contralateral forehead flattening, ipsilateral cheek anteriorly displaced	Temporal bossing, increase in vertical height in severe cases
Other	Torticollis, head position preference	Large size, history of limited activity or limited mobility

SEVERITY

	LATERAL DEFORMATIONAL PLAGIOCEPHALY			POSTERIOR DEFORMATIONAL PLAGIOCEPHALY (BRACHYCEPHALY)	
Mild	TDD 3-10 mm	Type I	Flattening restricted to the back of the skull	CI: 0.82-0.9	Central posterior deformity ("ping-pong ball depression")
Moderate	TDD 10-12 mm	Type II	Malposition of ear	CI: 0.9-1.0	Central posterior deformity and widening of posterior skull
		Type III	Forehead deformity		
Severe	TDD >12 mm	Type IV	Malar deformity	CI: >1.0	Vertical head, head growth, or temporal bossing
		Type V	Vertical or temporal skull growth		

CI, cephalic index (cranial index); TDD, transcranial diameter difference.

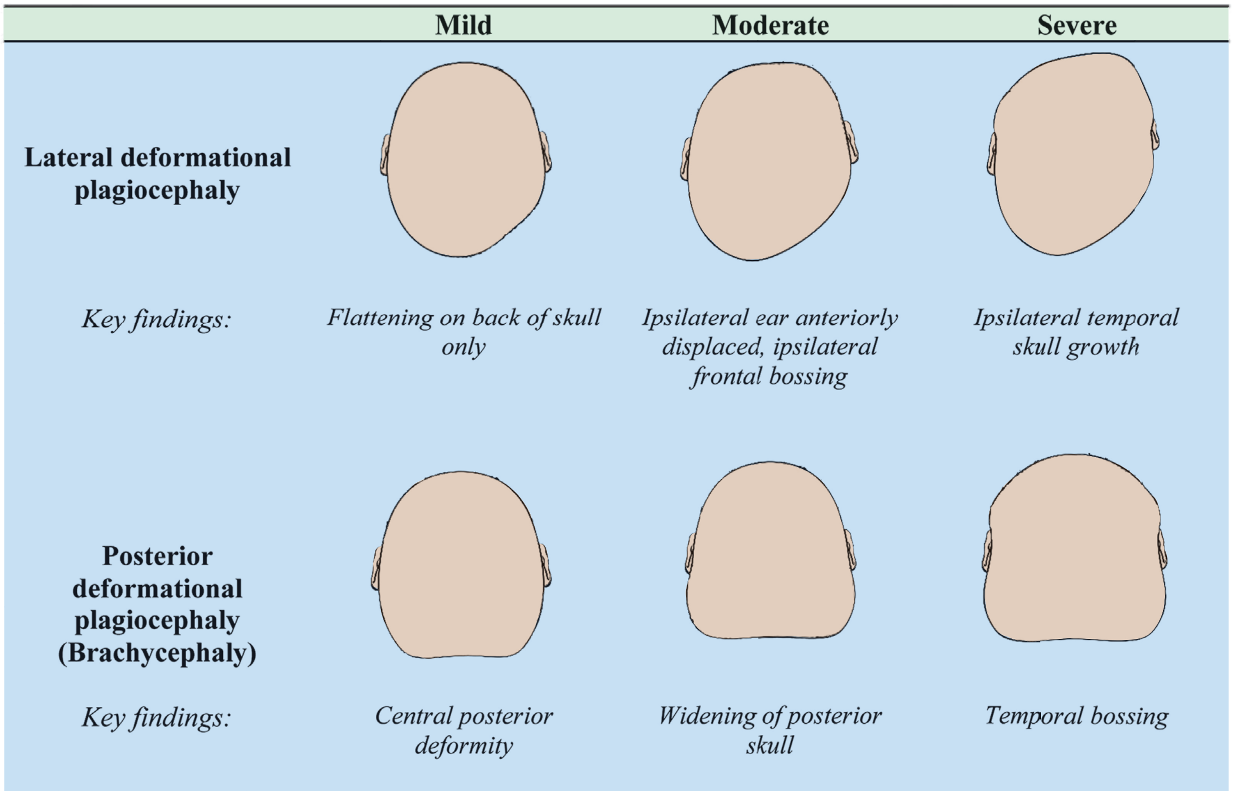

Figure 592-3 Types of deformational plagiocephaly. *(From Looman WS, Flannery AB: Evidence-based care of the child with deformational plagiocephaly, part I: assessment and diagnosis.* J Pediatr Health Care *26:242–250, 2012, Fig. 1.)*

an obvious positional preference to a particular side will take more time and effort in purposefully repositioning them counter to their preference. Parents must be counseled in the benefit of this strategy in preventing bald spots or flat spots that can progress to cranial deformity.

"Tummy time" is the term used to describe the infant's awake time spent lying on their stomach. The suggested amount of tummy time is **10-15 minutes at least 3 times a day**. Reassure parents that sleep is the only time during which the prone position should be avoided, and educate the parents as to the benefits for the infant of awake prone positioning to help progression of motor development.

Treatment Options

Cranial asymmetry from DP does not usually spontaneously improve, nor do the more-severe manifestations of facial and ear asymmetry disappear. Once a flat spot develops, it is unlikely that the infant will be able to overcome the pull to lie on the same spot in time to allow for reversal of the asymmetry.

"Watch-and-wait" management is not recommended in infants with DP. Evidence suggests that, at a minimum, repositioning and physiotherapy should be initiated as soon as asymmetry is observed.

Repositioning and physiotherapy (RPPT) include the counseling and teaching for parents as to positional changes and tummy time in their child as well as **referral to physical therapy in the case of congenital torticollis.** RPPT is the optimal treatment choice for patients younger than 4 mo of age who have mild or moderately severe DP. The earliest types of behavioral modifications can be as simple as increasing tummy time, or repositioning the infant's crib such that everything interesting in the room is on the side opposite the DP.

Molding therapy (helmet therapy) is the use of an orthotic helmet to promote the resolution of cranial asymmetry while the infant's head is still rapidly growing. Orthotic helmets do not actively mold the skull; rather, they protect the areas that are flat and allow the child to "grow into" the flat spot. Studies have shown helmet therapy to achieve correction 3 times faster and better than repositioning alone. This therapy is still debated because of its expense, time requirements, coverage and side effects (irritation, rashes, and pressure sores). The most recent studies suggest that **combined treatment with helmet therapy and RPPT is the most beneficial management of infants older than 4 mo with severe DP or with worsening of mild/moderate DP trialed on RPPT.** Infants with severe DP should be considered for helmet therapy at any age.

Studies suggest helmet therapy should be started for significant DP between 4 and 8 mo and continued for 7-8 mo. Parents should be counseled on the commitment involved in this treatment as helmets need to be worn more than 20 hr a day.

Patients with craniosynostosis require surgery. Sometimes, a molding helmet can be used as an adjunctive therapy after surgery but never as monotherapy.

OUTCOMES

Outcomes may be better when helmet therapy is started before 6 mo of age, and infants starting therapy later than that do not achieve the same degree of normal head measurements as those whose helmet therapy is started before 6 mo of age do. Significant improvements in asymmetry are usually obvious at 4-11 wk after initiation of helmet therapy.

Studies in patients with a median follow-up age of 9 yr old found that 75% of cases had a what both parents and patients considered to be a normal head appearance. Nine percent of patients and 4% of parents noted residual asymmetry that they considered significant.

Cognitive and academic outcomes may be different depending on the side of deformity. Poorer academic performance and greater speech abnormalities were found in patients with left-sided deformities compared to those with right-sided deformities. This manifested as double the number of patients with expressive speech abnormalities and triple the number of special education needs. It is unclear what the underlying mechanism is; treatment differences were apparently not a factor. In general, children with DP and without comorbid conditions are usually developmentally normal, healthy children. This is in contrast to craniosynostosis, in which increases in intracranial pressure may have deleterious effects on central nervous system function.

Chapter 593

Seizures in Childhood

Mohamad A. Mikati and Abeer J. Hani

A seizure is a transient occurrence of signs and/or symptoms resulting from abnormal excessive or synchronous neuronal activity in the brain. The International Classification of Epileptic Seizures divides epileptic seizures into 2 large categories: In **focal (formerly known as partial) seizures,** the first clinical and electroencephalographic (EEG) changes suggest initial activation of a system of neurons limited to part of 1 cerebral hemisphere. The term *simple partial seizures* is an outdated classification that refers to focal seizures with no alteration in consciousness whereas complex partial seizures, currently also referred to as focal dyscognitive, denote focal seizures with altered awareness of the surroundings. In **generalized seizures,** the first clinical and EEG changes indicate synchronous involvement of all of both hemispheres (Table 593-1). Approximately 30% of patients who have a first afebrile seizure have later epilepsy; the risk is approximately 20% if neurologic exam, EEG, and neuroimaging are normal. **Febrile seizures** are a separate category. **Acute symptomatic seizures** occur secondary to an acute problem affecting brain excitability such as electrolyte imbalance. Most children with these types of seizures do well. However, sometimes these seizures signify major structural, inflammatory, or metabolic disorders of the brain, such as meningitis, encephalitis, acute stroke, or brain tumor. Consequently, the prognosis depends on the underlying disorder, including its reversibility or treatability and the likelihood of developing epilepsy from it. An **unprovoked seizure** is one that is not an acute symptomatic seizure. **Remote symptomatic seizure** is one that is considered to be secondary to a distant brain injury, such as an old stroke. **Reflex seizures** are usually precipitated by a sensory stimulus such as flashing lights (see Chapter 593.9).

Epilepsy is a disorder of the brain characterized by an enduring predisposition to generate seizures and by the neurobiologic, cognitive, psychologic, and social consequences of this condition. The clinical diagnosis of epilepsy usually requires the occurrence of at least 1 unprovoked epileptic seizure with either a second such seizure or enough EEG and clinical information to convincingly demonstrate an enduring predisposition to develop recurrences. For epidemiologic and commonly for clinical purposes, epilepsy is considered to be present when 2 or more unprovoked seizures occur in a time frame of longer than 24 hr. Approximately 4-10% of children experience at least 1 seizure (febrile or afebrile) in the 1st 16 yr of life. The cumulative lifetime incidence of epilepsy is 3%, and more than half of the cases start in childhood. The annual prevalence is 0.5-1.0%. Thus, the occurrence of a single seizure or of febrile seizures does not necessarily imply the diagnosis of epilepsy. **Seizure disorder** is a general term that is usually used to include any 1 of several disorders, including epilepsy, febrile seizures, and possibly single seizures and symptomatic seizures secondary to metabolic, infectious, or other etiologies (e.g., hypocalcemia, meningitis).

An **epileptic syndrome** is a disorder that manifests 1 or more specific seizure types and has a specific age of onset and a specific prognosis. Several types of epileptic syndromes can be distinguished

Table 593-1 Types of Epileptic Seizures

SELF-LIMITED SEIZURE TYPES	CONTINUOUS SEIZURE TYPES
Focal Seizures	***Generalized Status Epilepticus***
Focal sensory seizures	Generalized tonic-clonic status epilepticus
• With elementary sensory symptoms (e.g., occipital and parietal lobe seizures)	Clonic status epilepticus
• With experiential sensory symptoms (e.g., temporoparietooccipital junction seizures)	Absence status epilepticus
Focal motor seizures	Tonic status epilepticus
• With elementary clonic motor signs	Myoclonic status epilepticus
• With asymmetrical tonic motor seizures (e.g., supplementary motor seizures)	***Focal Status Epilepticus***
• With typical (temporal lobe) automatisms (e.g., mesial temporal lobe seizures)	Epilepsia partialis continua of Kojevnikov
• With hyperkinetic automatisms	Aura continua
• With focal negative myoclonus	Limbic status epilepticus (psychomotor status)
• With inhibitory motor seizures	Hemiconvulsive status with hemiparesis
Gelastic seizures	PRECIPITATING STIMULI FOR REFLEX SEIZURES
Hemiclonic seizures	Visual stimuli
Secondarily generalized seizures	• Flickering light—color to be specified when possible
Reflex seizures in focal epilepsy syndromes	• Patterns
Generalized Seizures	• Other visual stimuli
Tonic-clonic seizures (includes variations beginning with a clonic or myoclonic phase)	Thinking
Clonic seizures	Music
• Without tonic features	Eating
• With tonic features	Praxis
Typical absence seizures	Somatosensory
Atypical absence seizures	Proprioceptive
Absence with special features:	Reading
• Eyelid myoclonia	Hot water
• Myoclonic absence	Startle
Tonic seizures	
Myoclonic seizures	
Myoclonic atonic seizures	
Negative myoclonus	
Atonic seizures	
Reflex seizures in generalized epilepsy syndromes	
Unknown	
Epileptic Spasms	

Modified from Berg AT, Berkovic SF, Brodie MJ et al: Revised terminology and concepts for organization of seizures and epilepsies: report of the ILAE Commission on Classification and Terminology, 2005–2009. Epilepsia *51(4):676–685, 2010.*

(Tables 593-2 to 593-5). This classification has to be distinguished from the classification of epileptic seizures that refers to single events rather than to clinical syndromes. In general, seizure type is the primary determinant of the type of medications the patient is likely to respond to, and the epilepsy syndrome determines the type of prognosis one could expect. An **epileptic encephalopathy** is an epilepsy syndrome in which there is a severe EEG abnormality which is thought to result in cognitive and other impairments in the patient. **Idiopathic epilepsy** is an older term that refers to an epilepsy syndrome that is genetic or presumed genetic and in which there is no underlying disorder affecting development or other neurologic function (e.g., petit mal epilepsy). In the International League Against Epilepsy (ILAE) classification of etiology of epilepsy, idiopathic epilepsy was replaced by the term **genetic epilepsy**, which implies that the epilepsy syndrome is the direct result of a known or presumed genetic defect(s) in which the genetic defect is not causative of a brain structural or metabolic disorder other than the epilepsy. **Symptomatic epilepsy** is also an older term referring to an epilepsy syndrome caused by an underlying brain disorder that may or may not be genetic (e.g., epilepsy secondary to tuberous sclerosis or to an old stroke); this is referred to as **structural/metabolic epilepsy**, which would be caused by a distinct structural or metabolic entity that increases the risk for seizures and causes the epilepsy. The older terms of **cryptogenic epilepsy** or of presumed **symptomatic epilepsy** refer to an epilepsy syndrome in which there is a presumed underlying brain disorder causing the epilepsy and affecting neurologic function, but the underlying disorder is not known; this is referred to as the **unknown epilepsy**, designating that the underlying cause of the epilepsy is as yet unknown.

EVALUATION OF THE FIRST SEIZURE

Initial evaluation of an infant or child during or shortly after a suspected seizure should include an assessment of the adequacy of the airway, ventilation, and cardiac function, as well as measurement of temperature, blood pressure, and glucose concentration. For acute evaluation of the first seizure, the physician should search for potentially life-threatening causes of seizures such as meningitis, systemic sepsis, unintentional or nonaccidental intentional head trauma, and ingestion of drugs of abuse or accidental ingestion of drugs or of other toxins. The history should attempt to define factors that might have promoted the convulsion and to provide a detailed description of the seizure and the child's postictal state (see Chapter 593.9). Most parents vividly recall their child's initial convulsion and can describe it in detail.

The subsequent step in an evaluation is to determine whether the seizure has a focal onset or is generalized. **Focal seizures** may be characterized by motor or sensory symptoms, which could include forceful turning of the head and eyes to 1 side, unilateral clonic movements beginning in the face or extremities, or a sensory disturbance, such as paresthesias or pain localized to a specific area. Focal seizures in an adolescent or adult usually indicate a localized lesion, whereas these seizures during childhood are often, but not always, secondary to a

Table 593-2 Classification for Epilepsy Syndromes with an Indication of Age of Onset, Duration of Active Epilepsy, Prognosis, and Therapeutic Options

SPECIFIC SYNDROMES	AGE AT ONSET	AGE AT REMISSION	PROGNOSIS	MONOTHERAPY OR ADD-ON*	POSSIBLE ADD-ON†	SURGERY†
EPILEPSIES OF UNKNOWN CAUSE OF INFANCY AND CHILDHOOD						
Benign infantile seizures (nonfamilial)	Infant	Infant	Good	PB	—	No
Benign childhood epilepsy with centrotemporal spikes	3-13 yr	16 yr	Good	CBZ, LEV, OXC, VPA	—	No
Early and late-onset idiopathic occipital epilepsy	2-8 yr; 6-17 yr	12 yr or younger; 18 yr	Good	CBZ, LEV, OXC, VPA	—	No
FAMILIAL (AUTOSOMAL DOMINANT) EPILEPSIES						
Benign familial neonatal convulsions	Newborn to young infant	Newborn to young infant	Good	PB	—	No
Benign familial infantile convulsions	Infant	Infant	Good	CBZ, PB	—	No
Autosomal dominant nocturnal frontal lobe epilepsy	Childhood		Variable	CBZ, GBP, OXC, PHT, TPM	CLB, LEV, PB, PHT	No
Familial lateral temporal lobe epilepsy	Childhood to adolescence		Variable	CBZ, GBP, OXC, PHT, TPM, VPA	CLB, LEV, PB, PHT	No
Generalized epilepsies with febrile seizures plus	Childhood to adolescence		Variable	ESM, LTG, TPM, VPA	CLB, LEV	No
STRUCTURAL–METABOLIC FOCAL EPILEPSIES						
Limbic Epilepsy						
Mesial temporal lobe epilepsy with hippocampal sclerosis	School-age or earlier	Long lasting	Variable	CBZ, LEV, OXC, TPM, VPA	CLB, GBP, LAC, PB, PHT, ZON	Temporal resection
Mesial temporal lobe epilepsy defined by specific causes	Variable	Long lasting	Variable	CBZ, LEV, OXC, TPM, VPA	CLB, GBP, LAC, PB, PHT, ZON	Temporal resection
Other types defined by location and causes	Variable	Long lasting	Variable	CBZ, LEV, OXC, TPM, VPA	CLB, FBM, GBP, LAC, PB, PHT, ZON	Lesionectomy ± temporal resection
Neocortical Epilepsies						
Rasmussen syndrome	6-12 yr	Progressive	Ominous	Plasmapheresis, immunoglobulins	CBZ, LAC, PB, PHT, TPM	Functional hemispherectomy
Hemiconvulsion-hemiplegia syndrome	1-5 yr	Chronic	Severe	CBZ, LEV, OXC, TPM, VPA	CLB, GBP, LAC, PB, PHT, ZON	Functional hemispherectomy
Other types defined by location and cause	Variable	Long lasting	Variable	CBZ, LEV, OXC, TPM, VPA	PHT, PB, CLB, GBP, LAC, ZON	Lesionectomy ± cortical resection
Migrating partial seizures of early infancy	Infant	No remission	Ominous	Bromides, CBZ, LEV, PB, PHT, TPM, VPA	BDZ, LAC, ZON	No
GENERALIZED EPILEPSIES OF UNKNOWN CAUSE						
Benign myoclonic epilepsy in infancy	3 mo-3 yr	3-5 yr	Variable	LEV, TPM, VPA	BDZ, ZON	No
Epilepsy with myoclonic astatic seizures	3-5 yr	Variable	Variable	ESM, TPM, VPA	BDZ, ketogenic diet, LEV, LTG, steroids, ZON	No
Childhood absence epilepsy	5-6 yr	10-12 yr	Good	ESM, LTG, VPA	Acetazolamide, ketogenic diet, ZON	No
Epilepsy with myoclonic absences	1-12 yr	Variable	Guarded	ESM, VPA	BDZ, ZON	No

*Reflects current trends in practice, which may be off-label and may not be FDA approved for that indication. See Table 593-10 for FDA indications.

†May apply to selected cases only. Vagus nerve stimulation has been used for all types of refractory seizures and epilepsy types.

ACTH, adrenocorticotropic hormone; BDZ, benzodiazepine; CBZ, carbamazepine; CLB, clobazam; DZP: diazepam; ESM, ethosuximide; FBM: felbamate; GBP, gabapentin; IVIG, intravenous immunoglobulin; LAC, lacosamide; LEV, levetiracetam; LTG, lamotrigine; n/a, not applicable; OXC: oxcarbazepine; PB, phenobarbital; PHT, phenytoin; PRM, primidone; RFD, rufinamide; TPM, topiramate; VGB: vigabatrin; VPA, valproic acid; ZON, zonisamide.

Table 593-2 Classification for Epilepsy Syndromes with an Indication of Age of Onset, Duration of Active Epilepsy, Prognosis, and Therapeutic Options—cont'd

SPECIFIC SYNDROMES	AGE AT ONSET	AGE AT REMISSION	PROGNOSIS	MONOTHERAPY OR ADD-ON*	POSSIBLE ADD-ON†	SURGERY†
GENERALIZED EPILEPSIES OF UNKNOWN CAUSE WITH VARIABLE PHENOTYPES						
Juvenile absence epilepsy	10-12 yr	Usually lifelong	Good	ESM, LTG, VPA	BDZ	No
Juvenile myoclonic epilepsy	12-18 yr	Usually lifelong	Good	LEV, TPM, VPA	BDZ, LTG, PB, PRM, ZON	No
Epilepsy with generalized tonic-clonic seizures only	12-18 yr	Usually lifelong	Good	LEV, LTG, TPM, VPA	BDZ, CBZ, ZON	No
REFLEX EPILEPSIES						
Idiopathic photosensitive occipital lobe epilepsy	10-12 yr	Unclear	Variable	VPA	BDZ, LEV, LTG, ZON	No
Other visual sensitive epilepsies	2-5 yr	Unclear	Variable	VPA	BDZ, LEV, LTG, ZON	No
Startle epilepsy	Variable	Long lasting	Guarded	CBZ, GBP, OXC, PHT, TPM, VPA	CLB, LEV, PB, PHT, ZON	Lesionectomy ± cortical resection in some
EPILEPTIC ENCEPHALOPATHIES						
Early myoclonic encephalopathy and Ohtahara syndrome	Newborn-infant	Poor, Ohtahara syndrome evolves into West syndrome	Ominous	PB, steroids, VGB	BDZ, ZON	No
West syndrome	Infant	Variable	Variable	ACTH, steroids, VGB	BDZ, FBM, IVIG, TPM, ZON	Lesionectomy ± cortical resection
Dravet syndrome (severe myoclonic epilepsy in infancy)	Infant	No remission	Severe	CLB, stiripentol, TPM, VPA	BDZ, ZON	No
Lennox-Gastaut syndrome	3-10 yr	No remission	Severe	CLB, LTG, RFD, TPM, VPA	BDZ, FBM, IVIG, steroids, ZON	Callosotomy
Landau-Kleffner syndrome	3-6 yr	8-12 yr	Guarded	LEV, nocturnal DZP, steroids, VPA	BDZ, ESM, IVIG, LTG	Multiple subpial transections, rarely lesionectomy
Epilepsy with continuous spike waves during slow-wave sleep	4-7 yr	8-12 yr	Guarded	LEV, nocturnal DZP, steroids, VPA	BDZ, ESM, IVIG, LTG	No
PROGRESSIVE MYOCLONUS EPILEPSIES						
Unverricht-Lundborg, Lafora, ceroid lipofuscinoses, etc.	Late infant to adolescent	Progressive	Ominous	TPM, VPA, ZON	BDZ, PB	No
OTHER EPILEPSIES AND SEIZURE DISORDERS OF UNKNOWN OR OTHER CAUSES						
Benign neonatal seizures	Newborn	Newborn	Good	LEV, PB	—	No
Febrile seizures	3-5 yr	3-6 yr	Good	PB or VPA if repeated and prolonged	—	No
Reflex seizures	Variable	n/a		LEV, VPA	LTG, ZON	No
Drug or other chemically induced seizures	Variable	n/a		Withdraw offending agent	—	No
Immediate and early posttraumatic seizures	Variable	n/a		LEV, PHT	—	No

Table 593-3 Identified Genes for Epilepsy Syndromes*†

EPILEPSY TYPE	GENE	PROTEIN
INFANTILE ONSET		
Benign familial neonatal seizures	*KCNQ2*	Potassium voltage-gated channel
	KCNQ3	Potassium voltage-gated channel
Benign familial neonatal infantile seizures	*SCN2A*	Sodium channel protein type 2α
Early familial neonatal infantile seizures	*SCN2A*	Sodium channel protein type 2α
Early infantile epileptic encephalopathy (EIEE)	*CDKL5 (EIEE2)*	Cyclin-dependent kinase-like 5
	ARX (EIEE1)	Aristaless-related homeobox
	TSC1	Hamartin
	TSC2	Tuberin
	SCN1A (EIEE6)	Sodium channel protein type 1α
	PCDH19(EIEE9)	Protocadherin-19
	KCNQ2 (EIEE7)	Potassium voltage-gated channel
	STXBP1 (EIEE4)	Syntaxin binding protein 1
	SLC2A1	Solute carrier family 2, facilitated glucose transporter member 1
	ALDH7A1	α-Aminoadipic semialdehyde dehydrogenase (antiquitin)
	POLG	DNA polymerase subunit gamma-1
	SCN2A (EIEE11)	Sodium channel protein type 2α
	PLCβ1 (EIEE12)	Phospholipase C β1
	ATP6AP2	Renin receptor
	SPTAN1 (EIEE5)	α_2-Spectrin
	SLC25A22 (EIEE3)	Mitochondrial glutamate carrier 1
	PNPO	Pyridoxine-5′-phosphate oxidase
Generalized epilepsy with febrile seizures plus (early onset)	*SCN1A*	Sodium channel protein type 1α
	SCN1B	Sodium channel protein type 1β
	GABRG2	γ-Aminobutyric acid receptor subunit γ2
	SCN2A	Sodium channel protein type 1α
CHILDHOOD ONSET		
Childhood onset epileptic encephalopathies	*SCN1A*	Sodium channel protein type 1α
	PCDH19	Protocadherin-19
	SLC2A1	Solute carrier family 2, facilitated GTM1
	POLG	DNA polymerase subunit γ1
	SCN2A	Sodium channel protein type 2α
Early onset absence seizures, refractory epilepsy of multiple types at times with movement disorder	*GLUT-1* deficiency syndrome, *SLC2A1*gene	Solute carrier family 2, facilitated GTM1
Generalized epilepsy with febrile seizure plus	*SCN1A*	Sodium channel protein type 1α
	SCN1B	Sodium channel protein type 1β
	GABRG2	γ-Aminobutyric acid receptor subunit γ2
	SCN2A	Sodium channel protein type 1α
Juvenile myoclonic epilepsy (more commonly presents in adolescence)	*EFHC1*	EF-hand domain-containing protein 1
	CACNB4	Voltage-dependent L-type calcium channel
	GABRA1	γ-Aminobutyric acid receptor subunit α1
Progressive myoclonic epilepsy (different forms present from infancy through adulthood)	*EPM2A*	Laforin
	NHLRC1	NHL repeat-containing protein 1 (Malin)
	CSTB	Cystatin-B
	PRICKLE1	Prickle-like protein 1
	PPT1, TPP1,CLN3, CLN5, CLN6, CLN8, CTSD, DNAJC5, MFSD8	Multiple proteins causing neuronal ceroid lipofuscinosis
Autosomal dominant nocturnal frontal lobe epilepsies (presents in childhood through adulthood)	*CHRNA4*	Neuronal acetylcholine receptor α4
	CHRNB2	Neuronal acetylcholine receptor β2
	CHRNA2	Neuronal acetylcholine receptor α2
ADOLESCENT ONSET		
Juvenile myoclonic epilepsy (JME)	See Childhood Onset JME	
Progressive myoclonic epilepsy (PME)	See Childhood Onset PME	
Autosomal dominant nocturnal frontal lobe epilepsies (AD-NFLE)	See Childhood Onset AD-NFLE	
Autosomal dominant lateral temporal lobe epilepsy (AD-LTLE)	See Childhood Onset AD-LTLE	
Autosomal dominant lateral temporal lobe epilepsy (usually presents in adulthood)	*LGI1*	Leucine-rich glioma-inactivated protein 1

*Note that the same gene (different mutations) often appears as causing different epilepsy syndromes.

†Most of these genes can be tested for through commercially available targeted single-gene sequencing or through commercially available gene panels or though exome sequencing (http://www.ncbi.nlm.nih.gov/sites/GeneTests/review?db=genetests).

Table 593-4 Identified Genes for Syndromic Epilepsy Syndromes*

SYNDROME	GENE	PROTEIN
Rett/atypical Rett syndromes	*MECP2* *CDKL5* *FOXG1* *MBD5* *MEF2C*	Methyl CpG binding protein 2 Cyclin-dependent kinase-like 5 Forkhead box protein G1 Methyl-CpG-binding domain protein 5 Myocyte-specific enhancer factor 2C
Angelman/Angelman-like/Pitt-Hopkins syndromes	*UBE3A* *SLC9A6* *MBD5* *TCF4* *NRXN1* *CNTNAP2*	Ubiquitin protein ligase E3A Sodium/hydrogen exchanger 6 Methyl-CpG-binding domain protein 5 Transcription factor 4 Neurexin-1 Contactin-associated protein-like 2
Mowat-Wilson syndrome	*ZEB2*	Zinc finger E-box-binding homeobox 2
Creatine deficiency syndromes	*GAMT* *GATM*	Guanidinoacetate *N*-methyltransferase Glycine amidinotransferase, mitochondrial
Neuronal ceroid lipofuscinosis (NCL)	*PPT1 (CLN1)* *TPP1 (CLN2)* *CLN3* *CLN5* *CLN6* *MFSD8 (CLN7)* *CLN8* *CTSD (CLN10)* *KCTD7 (CLN14)*	Palmitoyl-protein thioesterase 1 Tripeptidyl-peptidase 1 Battenin Ceroid-lipofuscinosis neuronal protein 5 Ceroid-lipofuscinosis neuronal protein 6 Major facilitator superfamily domain-containing protein 8 Ceroid-lipofuscinosis neuronal protein 8 Cathepsin D BTB/POZ domain-containing protein KCTD7
Adenosuccinate lyase deficiency	*ADSL*	Adenylosuccinate lyase
Cerebral folate deficiency	*FOLR1*	Folate receptor alpha
Epilepsy with variable learning and behavioral disorders	*GRIN2A* *SYN1*	Glutamate receptor ionotropic, *N*-methyl-D-aspartate (NMDA) 2A Synapsin-1
